Good code is like a love letter to the next developer who will maintain it!

Design patterns provide a common vocabulary to structure code, making it easier to understand. They help enhance the quality of this connection to other developers. Knowledge of design patterns helps us identify recurring themes in requirements and map them to definitive solutions. We can rely on the experience of others who have encountered a similar problem and devised an optimized method to address it. This knowledge is invaluable as it paves the way for writing or refactoring code to make it maintainable.

Whether on the server or client, JavaScript is a cornerstone of modern web application development. The **previous edition of this book** focused on several popular design patterns in the JavaScript context. Over the years, JavaScript has significantly evolved as a language in terms of features and syntax. It now supports modules, classes, arrow functions, and template literals that were not there earlier. We also have advanced JavaScript libraries and frameworks that have made life easy for many web developers. How

relevant, then, are Design Patterns in the modern JavaScript context?

It's important to note that traditionally design patterns are neither prescriptive nor language specific. You can apply them when you think they fit, but you don't have to. Like data structures or algorithms, you can still apply classic design patterns using modern programming languages, including JavaScript. You may not need some of these design patterns in modern frameworks or libraries where they are already abstracted. Conversely, the use of specific patterns may even be encouraged by some frameworks.

In this edition, we are taking a pragmatic approach to patterns. We will explore why specific patterns may be the right fit for implementing certain features and if a pattern it is still recommended in the modern JavaScript context.

As applications got more interactive, requiring a large amount of JavaScript, the language came under constant criticism for its negative impact on performance. Developers are continuously looking for new patterns that can optimize JavaScript performance. This edition highlights such improvements wherever relevant. We will also discuss framework-specific patterns such as React Hooks and Higher Order Components that have become increasingly popular in the age of React.js.

Going back a step, let us start by exploring the history and importance of design patterns. If you are already familiar with this history, feel free to skip to **“What Is a Pattern?”** to continue reading.

History of Design Patterns

Design patterns can be traced back to the early work of an architect named **Christopher Alexander**. He often wrote about his experiences in solving design issues and how they related to buildings and towns. One day, it occurred to Alexander that certain design constructs lead to a desired optimal effect when used repeatedly.

Alexander produced a pattern language in collaboration with two other architects, Sara Ishikawa and Murray Silverstein. This language would help

empower anyone wishing to design and build at any scale. They published it in 1977 in a paper titled “A Pattern Language,” later released as a complete hardcover **book**.

Around 1990, software engineers began to incorporate the principles Alexander had written about into the first documentation about design patterns to guide novice developers looking to improve their coding skills. It’s important to note that the concepts behind design patterns have been around in the programming industry since its inception, albeit in a less formalized form.

One of the first and arguably the most iconic formal works published on design patterns in software engineering was a book in 1995 called **Design Patterns: Elements of Reusable Object-Oriented Software**—written by Erich Gamma, Richard Helm, Ralph Johnson, and John Vlissides. Most engineers today recognize this group as the Gang of Four (or GoF for short).

The **GoF publication** is particularly instrumental in pushing the concept of design patterns further in our field. It describes several development techniques and pitfalls and provides 23 core object-oriented design patterns frequently used worldwide today. We will cover these patterns in more detail in **Chapter 6**, and they also form the basis for our discussion of **Chapter 7**.

What Is a Pattern?

A pattern is a reusable solution template that you can apply to recurring problems and themes in software design. Similar to other programming languages, when building a JavaScript web application, you can use the template to structure your JavaScript code in different situations where you think it will help.

Learning and using Design patterns is mainly advantageous for developers because:

Patterns are proven solutions.

They are the result of the combined experience and insights of developers

who helped define them. They are time-tested approaches known to work when solving specific issues in software development.

Patterns can be easily reused.

A pattern usually delivers an out-of-the-box solution you can adopt and adapt to suit your needs. This feature makes them quite robust.

Patterns can be expressive.

Patterns can help express elegant solutions to extensive problems using a set structure and a shared *vocabulary*.

Additional advantages that patterns offer are:

Patterns assist in preventing minor issues that can cause significant problems in the application development process.

When you use established patterns to build code, you can relax about getting the structure wrong and focus on the quality of the overall solution. The pattern encourages you to write more structured and organized code naturally, avoiding the need to refactor it for cleanliness in the future.

Patterns provide generalized solutions, documented in a fashion that doesn't require them to be tied to a specific problem.

This generalized approach means you can apply design patterns to improve code structure regardless of the application (and, in many cases, the programming language).

Some patterns can decrease the overall code file-size footprint by avoiding repetition.

Design patterns encourage developers to look more closely at their solutions for areas where they can achieve instant reductions in duplication. For example, you can reduce the number of functions performing similar processes in favor of a single generalized function to

decrease the size of your codebase. This is also known as making code more *dry*.

Patterns add to a developer's vocabulary, which makes communication faster.

Developers can reference the pattern when communicating with their team, discussing it in the design patterns community, or indirectly when another developer later maintains the code.

Popular design patterns can be improvised further by harnessing the collective experiences of developers using those patterns and contributing back to the community.

In some cases, this leads to the creation of entirely new design patterns, while in others, it can lead to improved guidelines on the usage of specific patterns. This can ensure that pattern-based solutions continue to become more robust than ad hoc ones.

NOTE

Patterns are *not* exact solutions. The role of a pattern is merely to provide us with a solution scheme. Patterns don't solve all design problems nor replace good software designers. You still need sound designers to choose the correct patterns that can enhance the overall design.

An everyday use case for design patterns

If you have used React.js, you have probably come across the Provider pattern. If not, you may have experienced the following situation.

The component tree in web applications often needs access to shared data like user information or user access permissions. The traditional way to do this in JavaScript is to set these properties for the root level component and then pass them down from parent to child components. As the component hierarchy deepens and becomes more nested, you drill down it with your data

resulting in the practice of prop-drilling. This leads to unmaintainable code where the property setting and passing will get repeated in every child component, which relies on that data.

React and a few other frameworks address this problem using the Provider Pattern. With the Provider pattern, the React Context API can broadcast the state/data to multiple components via a context provider. Child components needing the shared data can tap into this provider as a context consumer or use the useContext Hook.

This is an excellent example of a design pattern used to optimize the solution to a very common problem. We will cover this and many such patterns in a lot of detail in this book.

Summary

With that introduction to the importance of design patterns and their relevance to modern JavaScript, we can now deep dive into learning JavaScript Design Patterns. The first few chapters in this book talk about structuring and classifying patterns and identifying anti-patterns before we go into the specifics of design patterns for JavaScript. But first, let us see what it takes for a proposed “proto-pattern” to be recognized as a pattern in the next chapter.

Chapter 2. “Pattern”-ity Testing, Proto-Patterns, and the Rule of Three

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 2nd chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

From the moment a new pattern is proposed to its potential widespread adoption, a pattern may have to go through multiple rounds of deep inspection by the design community and software developers. This chapter talks about this journey of a newly introduced “Proto-Pattern” through a “pattern”-ity test till it is eventually recognized as a pattern if it meets the *Rule of Three*.

This and the next chapter explore the approach to structuring, writing, presenting, and reviewing nascent design patterns. If you’d prefer to learn established design patterns first, you can skip these two chapters for the time being.

What are Proto-Patterns?

Remember that not every algorithm, best practice, or solution represents what might be considered a complete pattern. There may be a few key ingredients missing, and the pattern community is generally wary of something claiming to be one without an extensive and critical evaluation. Even if something is presented to us which *appears* to meet the criteria for a pattern, we should not consider it as one until it has undergone suitable periods of scrutiny and testing by others.

Looking back upon Alexander's work once more, he claims that a pattern should both be a process and a "thing". This definition is obtuse as he follows by saying that it is the process that should create the "thing". This is why patterns generally focus on addressing a visually identifiable structure; we should be able to visually depict (or draw) a picture representing the structure resulting from placing the pattern into practice.

The "Pattern" Tests

You may often come across the term "proto-pattern" when studying design patterns. What is this? Well, a pattern that has not yet conclusively passed the "pattern"-ity tests is usually referred to as a proto-pattern. Proto-patterns may result from the work of someone who has established a particular solution worthy of sharing with the community. However, due to its relatively young age, the community has not had the opportunity to vet the proposed solution suitably.

Alternatively, the individual(s) sharing the pattern may not have the time or interest in going through the "pattern"-ity process and might release a short description of their proto-pattern instead. Brief descriptions or snippets of this type of pattern are known as patlets.

The work involved in comprehensively documenting a qualified pattern can be pretty daunting. Looking back at some of the earliest work in the field of design patterns, a pattern may be considered "good" if it does the following:

Solves a particular problem.

Patterns are not supposed to just capture principles or strategies. They

need to capture solutions. This is one of the most essential ingredients for a good pattern.

Does not have an obvious solution.

We can find that problem-solving techniques often attempt to derive from well-known first principles. The best design patterns usually provide solutions to issues indirectly—this is considered a necessary approach for the most challenging problems related to design.

Describes a proven concept.

Design patterns require proof that they function as described, and without this proof, the design cannot be seriously considered. If a pattern is highly speculative in nature, only the brave will attempt to use it.

Describes a relationship.

In some cases, it may appear that a pattern describes a type of module. Despite what the implementation looks like, the official description of the pattern must describe much deeper system structures and mechanisms that explain its relationship to code.

We would be forgiven for thinking that a proto-pattern that fails to meet guidelines isn't worth learning from; however, this is far from the truth. Many proto-patterns are actually quite good. I am not saying that all proto-patterns are worth looking at, but there are quite a few useful ones in the wild that could assist us with future projects. Use your best judgment with the above list in mind, and you'll be fine in your selection process.

Rule of Three

One of the additional requirements for a pattern to be valid is that they display some recurring phenomenon. You can often qualify this in at least three key areas, referred to as the *rule of three*. To show recurrence using this rule, one must demonstrate:

Fitness of purpose

How is the pattern considered successful?

Usefulness

Why is the pattern considered successful?

Applicability

Is the design worthy of being a pattern because it has broader applicability? If so, this needs to be explained. When reviewing or defining a pattern, it is vital to keep the above in mind.

Summary

This chapter has shown how every proposed proto-pattern may not always be accepted as a pattern. The next chapter shares the essential elements and best practices for structuring and documenting patterns so the community can easily understand and consume them.

Chapter 3. Structuring and Writing Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 3rd chapter of the final book.

The success of a new idea depends on its utility and also on how you present it to those it is trying to help. For developers to understand and adopt a design pattern, it should be presented with relevant information about the context, circumstances, prerequisites, and significant examples. This chapter applies to those trying to understand a specific pattern and those trying to introduce a new one as it provides essential information on how patterns are structured and written.

The Structure of a Design Pattern

Pattern authors would be unable to successfully create and publish a pattern if they cannot define its purpose. Similarly, developers will find understanding or implementing a pattern challenging if they do not have a background or context.

Pattern authors must outline a new pattern’s design, implementation, and

purpose. Authors initially present a new pattern in the form of a *rule* that establishes a relationship between:

- A context
- A system of forces that arises in that context
- A configuration that allows these forces to resolve themselves in context

With this in mind, let's now summarize the component elements for a design pattern. A design pattern should have the following, with the first five elements being the most important:

Pattern name

A unique name representative of the purpose of the pattern

Description

A brief description of what the pattern helps achieve.

Context outline

The contexts in which the pattern effectively responds to its users' needs.

Problem statement

A statement of the problem addressed so that we understand the pattern's intent.

Solution

A description of how the user's problem is solved in an understandable list of steps and perceptions.

Design

A description of the pattern's design and, in particular, the user's behavior in interacting with it.

Implementation

A guide to how developers would implement the pattern.

Illustrations

Visual representations of classes in the pattern (e.g., a diagram).

Examples

Implementations of the pattern in a minimal form.

Corequisites

What other patterns may be needed to support the use of the pattern being described?

Relations

What patterns does this pattern resemble? Does it closely mimic any others?

Known usage

Is the pattern being used in the wild? If so, where and how?

Discussions

The team or author's thoughts on the exciting benefits of the pattern.

Well Written Patterns

Understanding the structure and purpose of a design pattern can help us gain a deeper appreciation for the reasoning behind why a pattern is needed. It also helps us evaluate the pattern for our own needs.

A good pattern should ideally provide a substantial quantity of reference material for end users. Patterns should also provide evidence of why they are necessary.

Just having an overview of a pattern is not enough to help us identify them in the code we may encounter day-to-day. It's not always clear if a piece of

code we're looking at follows a set pattern or accidentally resembles one.

If you suspect that the code you see uses a pattern, consider writing down some aspects of the code that fall under a particular existing pattern or set of patterns. It may be that the code follows sound principles and design practices that coincidentally overlap with the rules for a specific pattern.

TIP

Solutions in which neither interactions nor defined rules appear are not patterns.

Although patterns may have a high initial cost in the planning and write-up phases, the value returned from that investment can be worth it. Patterns are valuable because they help to get all the developers in an organization or team on the same page when creating or maintaining solutions. If you are considering working on a pattern of your own, research beforehand, as you may find it more beneficial to use or extend existing, proven patterns rather than starting afresh.

Writing a pattern

If you are trying to develop a design pattern yourself, I recommend learning from others who have already been through the process and done it well. Spend time absorbing the information from several different design pattern descriptions and take in what's meaningful to you. Explore structure and semantics—you can do this by examining the interactions and context of the patterns you are interested in to identify the principles that assist in organizing those patterns together in valuable configurations.

You can utilize the *existing* format to write your own pattern or see if there are ways to improve it by integrating your ideas. An example of a developer that did this in recent years is Christian Heilmann, who took the existing *Module* pattern (see [Figure 7-2](#)) and made some fundamentally valuable changes to it to create the *Revealing Module* pattern (see [“The Revealing](#)

Module Pattern”).

Adhering to the following checklist would help if you are interested in creating a new design pattern or adapting an existing one:

How practical is the pattern?

Ensure that the pattern describes proven solutions to recurring problems rather than just speculative solutions that haven’t been qualified.

Keep best practices in mind.

Our design decisions should be based on principles we derive from understanding best practices.

Our design patterns should be transparent to the user.

Design patterns should be entirely transparent to the end-user experience. They primarily serve the developers using them and should not force changes to the expected user experience.

Remember that originality is not key in pattern design.

When writing a pattern, you do not need to be the original discoverer of the documented solutions, nor do you have to worry about your design overlapping with minor pieces of other patterns. If the approach is strong enough to have broadly applicable, it has a chance of being recognized as a valid pattern.

Patterns need a strong set of examples.

A good pattern description needs to be followed by an equally effective set of examples demonstrating the successful application of the pattern. To show broad usage, examples that exhibit sound design principles are ideal.

Pattern writing is a careful balance between creating a design that is general, specific, and above all, useful. Try to ensure that you comprehensively cover all possible application areas when writing a pattern.

Whether you write a pattern or not, I hope this brief introduction to writing patterns has given you some insights that will assist your learning process and help you rationalize the patterns covered in the following sections of this book.

Summary

This chapter painted a picture of the ideal “good” pattern. It is equally important to understand that “bad” patterns exist, too, so we can identify and avoid them. And that is why we have the next chapter about “Anti-Patterns”.

Chapter 4. Anti-Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 4th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

As engineers, we may run into situations when we are on a deadline to deliver a solution or where code gets included as a series of patches without a code review. The code in such cases may not always be well thought out and may propagate what we call *Anti-Patterns*. This chapter describes what Anti-Patterns are and why it is essential to understand and identify them. We also look at some typical anti-patterns in JavaScript.

What are Anti-Patterns

If a pattern represents a best practice, an anti-pattern represents the lesson learned when a proposed pattern goes wrong. Inspired by the GoF’s book *Design Patterns*, Andrew Koenig first coined the term Anti-Pattern in 1995 in his article in the *Journal of Object-Oriented Programming - Volume 8*. He described Anti-Patterns as:

An antipattern is just like a pattern, except that instead of a solution, it gives something that looks superficially like a solution but isn’t one.

He presented two notions of anti-patterns. Anti-patterns:

- Describe a *bad* solution to a particular problem that resulted in an unfavorable situation occurring
- Describe *how* to get out of the said situation and go to a good solution.

On this topic, Alexander writes about the difficulties in achieving a good balance between good design structure and good context:

These notes are about the process of design; the process of inventing physical things which display a new physical order, organization, form, in response to function....every design problem begins with an effort to achieve fitness between two entities: the form in question and its context. The form is the solution to the problem; the context defines the problem.

Understanding anti-patterns is as essential as being aware of design patterns. Let us qualify the reason behind this. When creating an application, a project's lifecycle begins with construction. At this stage, you are likely to choose from the available *good* design patterns as you see fit. However, after the initial release, it needs to be maintained.

Maintenance of an application already in production can be particularly challenging. Developers who haven't worked on the application before may accidentally introduce a *bad* design into the project. If said *bad* practices have already been identified as anti-patterns, developers will recognize these in advance and avoid the known common mistakes. This is similar to how knowledge of design patterns allows us to recognize areas where we could apply *known* and *helpful* standard techniques.

The quality of the solution as it evolves will either be *good* or *bad*, depending on the skill level and time the team has invested in it. Here, *good* and *bad* are considered in context—a 'perfect' design may qualify as an anti-pattern if applied in the wrong context.

To summarize, an anti-pattern is a bad design that is worthy of documenting.

Anti-Patterns in JavaScript

Developers sometimes knowingly opt for shortcuts and temporary solutions

to expedite code deliveries. These tend to become permanent and accumulate as technical debt that is essentially made up of anti-patterns. JavaScript is a weakly typed or untyped language that makes taking certain shortcuts easier. Following are some examples of anti-patterns that you might come across in JavaScript:

- Polluting the global namespace by defining numerous variables in the global context.
- Passing strings rather than functions to either `setTimeout` or `setInterval`, as this triggers the use of `eval()` internally.
- Modifying the `Object` class prototype (this is a particularly bad anti-pattern).
- Using JavaScript in an inline form as this is inflexible.
- The use of `document.write` where native DOM alternatives such as `document.createElement` are more appropriate. `document.write` has been grossly misused over the years and has quite a few disadvantages. If it's executed after the page has been loaded, it can overwrite the page we're on, which makes `document.createElement` a far better choice. Visit [this site](#) for a live example of this in action. It also doesn't work with XHTML, which is another reason opting for more DOM-friendly methods such as `document.createElement` is favorable.

Knowledge of anti-patterns is critical for success. Once we learn to recognize such anti-patterns, we can refactor our code to negate them so that the overall quality of our solutions improves instantly.

Summary

This chapter covered patterns that could cause problems known as Anti-Patterns and examples of JavaScript Anti-Patterns. Before we cover JavaScript design patterns in detail, we must touch upon some critical

modern JavaScript concepts that will prove relevant to our discussion on patterns. This is the subject for the next chapter that introduces modern JavaScript features and syntax.

Chapter 5. Modern JavaScript Syntax and Features

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 5th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

JavaScript has been around for many decades now and has undergone multiple revisions. This book explores design patterns in the modern JavaScript context and uses modern ES2015+ syntax for all the examples discussed. This chapter discusses ES2015+ JavaScript features and syntax essential to further our discussion of design patterns in the current JavaScript context.

NOTE

Some fundamental changes were introduced to JavaScript syntax with ES2015 that are especially relevant to our discussion on patterns. These are covered well in the [BabelJS ES2015 guide](#).

The Importance Of Decoupling Applications

Modular JavaScript allows you to logically split your application into smaller pieces called modules. A module can be imported by other modules that, in turn, can be imported by more modules. Thus, the application can be composed of many nested modules.

In the world of scalable JavaScript, when we say an application is **modular**, we often mean it's composed of a set of highly decoupled, distinct pieces of functionality stored in modules. Loose coupling facilitates easier maintainability of apps by removing *dependencies* where possible. If implemented efficiently, it allows you to see how changes to one part of a system may affect another.

Unlike some more traditional programming languages, the older iterations of JavaScript till ES5 (**Standard ECMA-262 5.1 Edition**) did not provide developers with the means to organize and import code modules cleanly. It was one of the concerns with the specifications that had not required great thought until more recent years when the need for more organized JavaScript applications became apparent. **AMD (Asynchronous Module Definition)** and **CommonJS** Modules were the most popular patterns to decouple applications in the initial versions of JavaScript.

Native solutions to these problems arrived with **ES6 or ES2015. TC39**, the standards body charged with defining the syntax and semantics of ECMAScript and its future iterations, had been keeping a close eye on the evolution of JavaScript usage for large-scale development and was acutely aware of the need for better language features for writing more modular JS.

The syntax to create modules in JavaScript was developed and standardized with the release of ECMAScript Modules in ES2015. Today, all major browsers support JavaScript modules. They have become the de-facto method of implementing modern-day modular programming in JavaScript. In this section, we'll explore code samples using the syntax for modules in ES2015+.

Modules With Imports And Exports

Modules allow us to separate our application code into independent units, each containing code for one aspect of the functionality. Modules also encourage code reusability and expose features that can be integrated into different applications.

A language should have features that allow you to `import` module dependencies and `export` the module interface (the public API/variables we allow other modules to consume) to support modular programming. The support for **JavaScript Modules (also referred to as ES Modules)** was introduced to JavaScript in ES2015, allowing you to specify module dependencies using an `import` keyword. Similarly, you can use the `export` keyword to export just about anything from within the module.

- **import** declarations bind a module's exports as local variables and may be renamed to avoid name collisions/conflicts.
- **export** declarations declare that a local binding of a module is externally visible such that other modules may read the exports but can't modify them. Interestingly, modules may export child modules but can't export modules that have been defined elsewhere. We can also rename exports so their external name differs from their local names.

NOTE

`.mjs` is an extension used for JavaScript modules that helps us distinguish between module files and classic scripts (`.js`). The `.mjs` extension ensures that corresponding files are parsed as a module by runtimes and build tools. (For example, `Node.js`, `Babel`)

The following example shows three modules for bakery staff, the functions they perform while baking, and the bakery itself. We see how functionality that is exported by one module is imported and used by the other.

```
// Filename: staff.mjs
// =====
```

```

// specify (public) exports that can be consumed by other
modules
export const baker = {
  bake(item) {
    console.log( `Woo! I just baked ${item}` );
  }
};

// Filename: cakeFactory.mjs
// =====
// specify dependencies
import baker from "/modules/staff.mjs";

export const oven = {
  makeCupcake(toppings) {
    baker.bake( "cupcake", toppings );
  },
  makeMuffin(mSize) {
    baker.bake( "muffin", size );
  }
}

// Filename: bakery.mjs
// =====
import {cakeFactory} from "/modules/cakeFactory.mjs";
cakeFactory.oven.makeCupcake( "sprinkles" );
cakeFactory.oven.makeMuffin( "large" );

```

Typically, a module file contains several related functions, constants, and variables. You can collectively export these at the end of the file using a single export statement followed by a comma-separated list of the module resources you want to export.

```

// Filename: staff.mjs
// =====
const baker = {
  //baker functions
};
const pastryChef = {
  //pastry chef functions
};

```

```
const assistant = {  
  //assistant functions  
};  
  
export { baker, pastryChef, assistant };
```

Similarly, you can only import the functions you need.

```
import {baker, assistant} from "/modules/staff.mjs";
```

You can tell browsers to accept 'script' tags that contain JavaScript modules by specifying the `type` attribute with a value of `module`:

```
<script type="module" src="main.mjs"></script>  
<script nomodule src="fallback.js"></script>
```

The `nomodule` attribute tells modern browsers not to load a classic script as a module. This is useful for fallback scripts that don't use the module syntax. It allows you to use the module syntax in your HTML and have it work in browsers that don't support it. This is useful for several reasons, including performance. Modern browsers don't require polyfilling for modern features, allowing you to serve the larger transpiled code to legacy browsers alone.

Module Objects

A cleaner approach to importing and using module resources is to import the module as an object. This makes all the exports available as members of the object.

```
// Filename: cakeFactory.mjs  
  
import * as Staff from "/modules/staff.mjs";  
  
export const oven = {  
  makeCupcake(toppings) {  
    Staff.baker.bake( "cupcake", toppings );  
  },  
};
```

```
    makePastry(mSize) {  
        Staff.pastryChef.make( "pastry", type );  
    }  
}
```

Modules Loaded From Remote Sources

ES2015+ also supports remote modules (e.g., third-party libraries), making it simplistic to load modules from external locations. Here's an example of pulling in the module we defined above and utilizing it:

```
import {cakeFactory} from  
"https://example.com/modules/cakeFactory.mjs"; // eagerly  
loaded static import  
  
cakeFactory.oven.makeCupcake( "sprinkles" );  
cakeFactory.oven.makeMuffin( "large" );
```

Static Imports

The type of import discussed above is called static import. The module graph needs to be downloaded and executed with static import before the main code can run. This can sometimes lead to the eager loading of a lot of code up front on the initial page load, which can be expensive and delay key features being available earlier.

```
import {cakeFactory} from "/modules/cakeFactory.mjs";  
// eagerly loaded static import  
  
cakeFactory.oven.makeCupcake( "sprinkles" );  
cakeFactory.oven.makeMuffin( "large" );
```

Dynamic Imports

Sometimes, you don't want to load a module up-front but on-demand when needed. Lazy-loading modules allows you to load what you need when

needed. For example, when the user clicks a link or a button. This improves the initial load-time performance. **Dynamic import** was introduced to make this possible.

Dynamic import introduces a new function-like form of import.

`import(url)` returns a promise for the module namespace object of the requested module, which is created after fetching, instantiating, and evaluating all of the module's dependencies, as well as the module itself. Here is an example that shows dynamic imports for the `cakeFactory` module.

```
form.addEventListener("submit", e => {
  e.preventDefault();
  import("/modules/cakeFactory.js")
    .then((module) => {
      // Do something with the module.
      module.oven.makeCupcake("sprinkles");
      module.oven.makeMuffin("large");
    });
});
```

Dynamic import can also be supported using the `await` keyword:

```
let module = await import("/modules/cakeFactory.js");
```

With dynamic import, the module graph is only downloaded and evaluated when the module is used.

Popular patterns like Import on Interaction and Import on Visibility can be easily implemented in vanilla JavaScript using the Dynamic Import feature.

Import on Interaction

Some libraries may only be required when a user starts interacting with a particular feature on the web page. Typical examples are chat widgets, complex dialog boxes, or video embeds. Libraries for these features need not be imported on page load but can be loaded when the user interacts with them

(for example, by clicking on the component facade or placeholder). The action can trigger the dynamic import of respective libraries followed by the function call to activate the desired functionality.

For example, you can implement an onscreen sort function using the external **lodash.sortby module**, which is loaded dynamically.

```
const btn = document.querySelector('button');

btn.addEventListener('click', e => {
  e.preventDefault();
  import('lodash.sortby')
    .then(module => module.default)
    .then(sortInput()) // use the imported dependency
    .catch(err => { console.log(err) });
});
```

Import on visibility

Many components are not visible on the initial page load but become visible as the user scrolls down. Since users may not always scroll down, modules corresponding to these components can be lazy-loaded when they become visible. The **IntersectionObserver API** can detect when a component placeholder is about to become visible, and a Dynamic import can load the corresponding modules.

Modules For The Server

Node 15.3.0 onwards supports JavaScript modules. They function without an experimental flag and are compatible with the rest of the npm package ecosystem. Node **treats** files ending in .mjs and .js with a top-level type field value of module as JavaScript Modules.

```
{
  "name": "js-modules",
  "version": "1.0.0",
  "description": "A package using JS Modules",
}
```

```
"main": "index.js",  
"type": "module",  
"author": "",  
"license": "MIT"  
}
```

Advantages of using Modules

Modular programming and the use of modules offer several unique advantages. Some of these are as follows:

Modules scripts are evaluated only once

The browser evaluates module scripts only once, while classic scripts get evaluated as often as they are added to the DOM. This means that with JS modules, if you have an extended hierarchy of dependent modules, the module that depends on the innermost module will be evaluated first. This is a good thing because it means that the innermost module will be evaluated first and will have access to the exports of the modules that depend on it.

Modules are auto-deferred

Unlike other script files, where you have to include the `defer` attribute if you don't want to load them immediately, browsers automatically defer the loading of modules.

Modules are easy to maintain and reuse

Modules promote decoupling pieces of code that can be maintained independently without significant changes to other modules. They also allow you to reuse the same code in multiple different functions.

Modules provide namespacing

Modules create a private space for related variables and constants so that they can be referenced via the module without polluting the global namespace.

Modules enable dead code elimination

Before the introduction of modules, unused code files had to be manually removed from projects. With module imports, bundlers such as **Webpack** and **rollup** can automatically identify unused modules and eliminate them. Dead code may be removed before adding it to the bundle. This is known as tree-shaking.

All modern browsers support module **import** and **export**, and you can use them without any fallback.

Classes With Constructors, Getters & Setters

In addition to modules, ES2015+ also allows defining classes with constructors and some sense of privacy. JavaScript Classes are defined with the **class** keyword. In the following example, we define a class **Cake** with a constructor and two getters and setters:

```
class Cake{

    // We can define the body of a class constructor
    // function by using the keyword constructor
    // with a list of class variables.
    constructor( name, toppings, price, cakeSize ){
        this.name = name;
        this.cakeSize = cakeSize;
        this.toppings = toppings;
        this.price = price;
    }

    // As a part of ES2015+ efforts to decrease the
    unnecessary
    // use of function for everything, you will notice that
    it is
    // dropped for cases such as the following. Here an
    identifier
    // followed by an argument list and a body defines a
    new method
```

```

    addTopping( topping ){
        this.toppings.push( topping );
    }

    // Getters can be defined by declaring get before
    // an identifier/method name and a curly body.
    get allToppings(){
        return this.toppings;
    }

    get qualifiesForDiscount(){
        return this.price > 5;
    }

    // Similar to getters, setters can be defined by using
    // the set keyword before an identifier
    set size( size ){
        if ( size < 0){
            throw new Error( "Cake must be a valid size: "
+
                                "either small, medium
or large");
        }
        this.cakeSize = size;
    }
}

// Usage
let cake = new Cake( "chocolate", ["chocolate chips"], 5,
"large" );

```

JavaScript classes are built on prototypes and are a special category of Javascript functions that need to be defined before they can be referenced.

You can also use the `extends` keyword to indicate that a class inherits from another class.

```

class BirthdayCake extends Cake {
    surprise() {
        console.log(`Happy Birthday!`);
    }
}

```

```

}

let birthdayCake = new BirthdayCake( "chocolate",
["chocolate chips"], 5, "large" );
birthdayCake.surprise();

```

All modern browsers and Node support ES2015 classes. They are also compatible with the **new-style class syntax** introduced in ES6.

The difference between JavaScript Modules and Classes is that Modules are **imported** and **exported**, and Classes are defined with the **class** keyword.

Reading through, one may also notice the lack of the word 'function' in the above examples. This isn't a typo error: TC39 has made a conscious effort to decrease our abuse of the **function** keyword for everything, hoping it will help simplify how we write code.

JavaScript classes also support the **super** keyword, which **allows** you to call a parent class' constructor. This is useful for implementing the **self-inheritance** pattern. You can use **super** to call the methods of the superclass.

```

class Cookie {
  constructor(flavor) {
    this.flavor = flavor;
  }

  showTitle() {
    console.log(`The flavor of this cookie is
${this.flavor}`);
  }
}

class FavoriteCookie extends Cookie {
  showTitle() {
    super.showTitle();
    console.log(`${this.flavor} is amazing.`);
  }
}

let myCookie = new FavoriteCookie('chocolate');
myCookie.showTitle();

```

```
// The flavor of this cookie is chocolate.  
// chocolate is amazing.
```

Modern JavaScript supports public and private class members. Public class members are accessible to other classes. Private class members are accessible only to the class in which they are defined. Class fields are, by default, public. **Private class fields** can be created by using the # hash prefix.

```
class CookieWithPrivateField {  
  #privateField;  
}  
  
class CookieWithPrivateMethod {  
  #privateMethod() {  
    return 'delicious cookies';  
  }  
}
```

JavaScript classes support static methods and properties using the `static` keyword. Static members can be referenced without instantiating the class. You can use static methods to create utility functions and static properties for holding configuration or cached data.

```
class Cookie {  
  constructor(flavor) {  
    this.flavor = flavor;  
  }  
  static brandName = "Best Bakes";  
  static discountPercent = 5;  
}  
console.log(Cookie.brandName); //output = "Best Bakes"
```

Classes in JavaScript frameworks

Over the last few years, some modern JavaScript libraries and frameworks—notably React—have introduced alternatives to classes. React Hooks make it possible to use React state and lifecycle methods without an ES2015 class component. Before Hooks, React developers had to refactor functional

components as class components so that they handle state and lifecycle methods. This was often tricky and required an understanding of how ES2015 classes work. React Hooks are functions that allow you to manage a component's state and lifecycle methods without relying on classes.

Note that several other approaches to building for the web, such as the **Web Components** community, continue to use classes as a base for component development.

Summary

This chapter introduced JavaScript language syntax for Modules and Classes. These features allow us to write code while adhering to object-oriented design and modular programming principles. We will also utilize these concepts to categorize and describe different design patterns. The next chapter talks about the different categories of design patterns.

Chapter 6. Categories of Design Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 6th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

This chapter documents the three main categories of design patterns and the different patterns that fall under them. While every design pattern addresses a specific object-oriented design problem or issue, we can draw parallels between the solutions based on how they solve these issues. This forms the basis for the categorization of design patterns.

Background

Gamma, Helm, Johnson & Vlissides (1995), in their book, **Design Patterns: Elements of Reusable Object-Oriented Software**, describe a design pattern as:

A design pattern names, abstracts, and identifies the key aspects of a common design structure that make it useful for creating a reusable object-oriented design. The design pattern identifies the participating classes and their instances, their roles and collaborations, and the distribution of responsibilities.

Each design pattern focuses on a particular object-oriented design problem or issue. It describes when it applies, whether or not it can be applied in view of other design constraints, and the consequences and trade-offs of its use. Since we must eventually implement our designs, a design pattern also provides sample ... code to illustrate an implementation.

Although design patterns describe object-oriented designs, they are based on practical solutions that have been implemented in mainstream object-oriented programming languages

Design patterns can be categorized based on the type of problem they solve. The three principal categories of design patterns are:

- Creational design patterns
- Structural design patterns
- Behavioral design patterns

In the following sections, we'll review these three with a few examples of the patterns that fall into each category.

Creational Design Patterns

Creational design patterns focus on handling object-creation mechanisms where objects are created in a manner suitable for a given situation. The basic approach to object creation might otherwise lead to added complexity in a project, while these patterns aim to solve this problem by *controlling* the creation process.

Some patterns that fall under this category are Constructor, Factory, Abstract, Prototype, Singleton, and Builder.

Structural Design Patterns

Structural patterns are concerned with object composition and typically

identify simple ways to realize relationships between different objects. They help ensure that when one part of a system changes, the entire structure of the system need not change. They also assist in recasting parts of the system that don't fit a particular purpose into those that do.

Patterns that fall under this category include Decorator, Facade, Flyweight, Adapter, and Proxy.

Behavioral Design Patterns

Behavioral patterns focus on improving or streamlining the communication between disparate objects in a system. They identify common communication patterns among objects and provide solutions that distribute the responsibility of communication among different objects, thereby increasing communication flexibility. Essentially, behavioral patterns abstract actions from objects that take the action

Some behavioral patterns include Iterator, Mediator, Observer, and Visitor.

Design Pattern Classes

Elyse Nielsen in 2004 created a “classes” table to summarize the 23 GOF design patterns. I found this table extremely useful in my early days of learning about design patterns. I've modified it where necessary to suit our discussion on design patterns.

I recommend using this table as a reference, but remember that we will discuss several other patterns not mentioned here later in the book.

NOTE

We discussed JavaScript ES2015+ classes in [Chapter 5](#). JavaScript classes and objects will be relevant when you review the following table.

Let us now proceed to review the table.

Creational	Based on the concept of creating an object
Class	
<i>Factory method</i>	Makes an instance of several derived classes based on interfaced data or events
Object	
<i>Abstract factory</i>	Creates an instance of several families of classes without detailing concrete classes
<i>Builder</i>	Separates object construction from its representation; always creates the same type of object
<i>Prototype</i>	A fully initialized instance used for copying or cloning
<i>Singleton</i>	A class with only a single instance with global access points
Structural	Based on the idea of building blocks of objects
Class	
<i>Adapter</i>	Matches interfaces of different classes so classes can work together despite incompatible interfaces
Object	

<i>Adapter</i>	Matches interfaces of different classes so classes can work together despite incompatible interfaces
<i>Bridge</i>	Separates an object's interface from its implementation so the two can vary independently
<i>Composite</i>	A structure of simple and composite objects that makes the total object more than just the sum of its parts
<i>Decorator</i>	Dynamically adds alternate processing to objects
<i>Facade</i>	A single class that hides the complexity of an entire subsystem
<i>Flyweight</i>	A fine-grained instance used for efficient sharing of information that is contained elsewhere
<i>Proxy</i>	A placeholder object representing the true object
Behavioral	Based on the way objects play and work together
Class	
<i>Interpreter</i>	A way to include language elements in an application to match the grammar of the intended language
<i>Template method</i>	Creates the shell of an algorithm in a method, then defers the exact steps to a subclass
Object	

<i>Chain of responsibility</i>	A way of passing a request between a chain of objects to find the object that can handle the request
<i>Command</i>	A way to separate the execution of a command from its invoker
<i>Iterator</i>	Sequentially accesses the elements of a collection without knowing the inner workings of the collection
<i>Mediator</i>	Defines simplified communication between classes to prevent a group of classes from referring explicitly to each other
<i>Memento</i>	Captures an object's internal state to be able to restore it later
<i>Observer</i>	A way of notifying change to a number of classes to ensure consistency between the classes
<i>State</i>	Alters an object's behavior when its state changes
<i>Strategy</i>	Encapsulates an algorithm inside a class, separating the selection from the implementation
<i>Visitor</i>	Adds a new operation to a class without changing the class

Summary

This chapter introduced categories of design patterns and explained the distinction between creational, structural, and behavioral patterns. We discussed the differences between these three categories and GOF patterns in

each category. We also reviewed the “classes” table that shows how the GOF patterns relate to the concepts of classes and objects.

These first few chapters have covered theoretical details about design patterns and some basics of JavaScript syntax. With this background, we are now in a position to job into some practical examples of design patterns in JavaScript.

Chapter 7. JavaScript Design Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 7th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

The previous chapter provided examples of the three different categories of design patterns. Some of these design patterns are relevant or required in the web development context. I have identified a few timeless patterns that can be helpful when applied in JavaScript. This chapter explores JavaScript implementations of different classic and modern design patterns. Every section is dedicated to one of the three categories—creational, structural, and behavioral. Let us begin with Creational patterns.

Choosing a Pattern

Developers commonly wonder whether there is an ideal pattern or set of patterns they should use in their workflow. There isn’t a single correct answer to this question; each script and web application we work on will likely have distinct individual needs. We must consider whether a pattern can offer real value to an implementation.

For example, some projects may benefit from the decoupling benefits offered by the Observer pattern (which reduces how dependent parts of an application are on one another). At the same time, others may be too small for decoupling to be a concern.

That said, once we have a firm grasp of design patterns and the specific problems they are best suited to, it becomes much easier to integrate them into our application architectures.

Creational Patterns

Creational patterns provide mechanisms to create objects. We will cover the following patterns.

- “The Constructor Pattern”
- “The Module Pattern”
- “The Revealing Module Pattern”
- “The Singleton Pattern”
- “The Prototype Pattern”
- “The Factory Pattern”

The Constructor Pattern

A constructor is a special method used to initialize a newly created object once the memory has been allocated for it. With ES2015+, the syntax for creating **classes** with constructors was introduced to JavaScript. This enables the creation of objects as an instance of a class using the default **constructor**.

In JavaScript, almost everything is an object, and classes are syntactic sugar for JavaScript’s prototypal approach to inheritance. With classic JavaScript, we were most often interested in object constructors. The figure **Figure 7-1** illustrates the pattern.

Example 7-1.

Object constructors are used to create specific types of objects—both preparing the object for use and accepting arguments to set the values of member properties and methods when the object is first created.

Figure 7-1. Constructor pattern

Object Creation

The three common ways to create new objects in JavaScript are as follows:

```
// Each of the following options will create a new empty object  
const newObject = {};  
  
// or  
const newObject = Object.create(Object.prototype);  
  
// or  
const newObject = new Object();
```

Here, we have declared each object as a constant, which creates a read-only block-scoped variable. In the final example, the `Object` constructor creates an object wrapper for a specific value, or where no value is passed; it creates an empty object and returns it.

You can now assign keys and values to an object in the following ways:

```
// ECMAScript 3 compatible approaches  
  
// 1. Dot syntax
```

```

// Set properties
newObject.someKey = "Hello World";

// Get properties
var key = newObject.someKey;

// 2. Square bracket syntax

// Set properties
newObject["someKey"] = "Hello World";

// Get properties
var key = newObject["someKey"];

// ECMAScript 5 only compatible approaches
// For more information see: http://kangax.github.com/es5-compat-table/

// 3. Object.defineProperty

// Set properties
Object.defineProperty( newObject, "someKey", {
    value: "for more control of the property's behavior",
    writable: true,
    enumerable: true,
    configurable: true
});

// 4. If the above feels a little difficult to read, a
// short-hand could
// be written as follows:

var defineProp = function ( obj, key, value ){
    config.value = value;
    Object.defineProperty( obj, key, config );
};

// To use, we then create a new empty "person" object
var person = Object.create( null );

```

```

// Populate the object with properties
defineProp( person, "car", "Delorean" );
defineProp( person, "dateOfBirth", "1981" );
defineProp( person, "hasBeard", false );

// 5. Object.defineProperty

// Set properties
Object.defineProperty( newObject, {

  "someKey": {
    value: "Hello World",
    writable: true
  },

  "anotherKey": {
    value: "Foo bar",
    writable: false
  }

});

// Getting properties for 3. and 4. can be done using any
of the
// options in 1. and 2.

```

You can even use these methods for inheritance as follows:

```

// ES2015+ keywords/syntax used: const
// Usage:

// Create a race car driver that inherits from the person
object
const driver = Object.create(person);

// Set some properties for the driver
defineProp(driver, 'topSpeed', '100mph');

// Get an inherited property (1981)
console.log(driver.dateOfBirth);

```

```
// Get the property we set (100mph)
console.log(driver.topSpeed);
```

Basic Constructors

As discussed earlier in [Chapter 5](#), JavaScript classes were introduced in ES2015, allowing us to define templates for JavaScript Objects and implement encapsulation and [inheritance](#) using JavaScript.

To recap, classes must include and declare a method named `constructor()` which will be used to instantiate a new object. The keyword `new` allows us to call the constructor. The keyword `this` inside a constructor references the new object created. The following example shows a basic constructor.

```
class Car {
  constructor(model, year, miles) {
    this.model = model;
    this.year = year;
    this.miles = miles;
  }

  toString() {
    return `${this.model} has done ${this.miles}
miles`;
  }
}
```

// Usage:

// We can create new instances of the car

```
let civic = new Car('Honda Civic', 2009, 20000);
let mondeo = new Car('Ford Mondeo', 2010, 5000);
```

*// and then open our browser console to view the output of
// the toString() method being called on these objects*

```
console.log(civic.toString());
console.log(mondeo.toString());
```

The above is a simple version of the constructor pattern but suffers from

some problems. One is that it makes inheritance difficult, and the other is that functions such as `toString()` are redefined for each new object created using the `Car` constructor. This isn't optimal as all of the instances of the `Car` type should ideally share the same function.

Constructors with Prototypes

Prototypes in JavaScript allow you to easily define methods for all instances of a particular object, be it a function or a class. When we call a JavaScript constructor to create an object, all the properties of the constructor's prototype are then made available to the new object. In this fashion, you can have multiple `Car` objects that access the same prototype. We can thus extend the original example as follows:

```
class Car {
  constructor(model, year, miles) {
    this.model = model;
    this.year = year;
    this.miles = miles;
  }
}

// Note here that we are using Object.prototype.newMethod
// rather than
// Object.prototype so as to avoid redefining the prototype
// object
// We still could use Object.prototype for adding new
// methods,
// because internally we use the same structure

Car.prototype.toString = function() {
  return `${this.model} has done ${this.miles} miles`;
};

// Usage:
let civic = new Car('Honda Civic', 2009, 20000);
let mondeo = new Car('Ford Mondeo', 2010, 5000);

console.log(civic.toString());
```

```
console.log(mondeo.toString());
```

Above, all Car objects will now share a single instance of the `toString()` method.

The Module Pattern

Modules are an integral piece of any robust application's architecture and typically help keep the units of code for a project cleanly separated and organized.

Classic JavaScript had several options for implementing modules, such as:

- Object literal notation
- The Module pattern
- AMD modules
- CommonJS modules

We have already discussed modern JavaScript modules (also known as “ES modules” or “ECMAScript modules,”) in the earlier chapter about [Chapter 5](#). We will primarily use ES modules for the examples in this section.

Before ES2015, CommonJS modules or AMD modules were popular alternatives as they allowed you to export the contents of a module. We will be exploring AMD, CommonJS, and UMD modules later on in the book in the section [Chapter 10](#). First, let us understand the Module Pattern and its origins.

The Module pattern is based partly on object literals, so it makes sense to refresh our knowledge of them first.

Object Literals

In object literal notation, an object is described as a set of comma-separated name/value pairs enclosed in curly braces (`{}`). Names inside the object may

be either strings or identifiers followed by a colon. It would be best if you did not use a comma after the final name/value pair in the object, as this may result in errors.

```
const myObjectLiteral = {
  variableKey: variableValue,
  functionKey() {
    // ...
  }
};
```

Object literals don't require instantiation using the `new` operator but shouldn't be used at the start of a statement as the opening `{` may be interpreted as the beginning of a new block. Outside of an object, new members may be added to it using the assignment as follows
`myModule.property = "someValue";`.

We can see a complete example of a module defined using object literal notation below:

```
const myModule = {
  myProperty: 'someValue',
  // object literals can contain properties and methods.
  // e.g we can define a further object for module
  configuration:
    myConfig: {
      useCaching: true,
      language: 'en',
    },
  // a very basic method
  saySomething() {
    console.log('Where is Paul Irish debugging
today?');
  },
  // output a value based on the current configuration
  reportMyConfig() {
    console.log(
      `Caching is: ${this.myConfig.useCaching ?
'enabled' : 'disabled'}`
    );
  }
};
```

```

    },
    // override the current configuration
    updateMyConfig(newConfig) {
        if (typeof newConfig === 'object') {
            this.myConfig = newConfig;
            console.log(this.myConfig.language);
        }
    },
};

// Outputs: What is Paul Irish debugging today?
myModule.saySomething();

// Outputs: Caching is: enabled
myModule.reportMyConfig();

// Outputs: fr
myModule.updateMyConfig({
    language: 'fr',
    useCaching: false,
});

// Outputs: Caching is: disabled
myModule.reportMyConfig();

```

Using object literals provided a way to encapsulate and organize code. Rebecca Murphey has previously written about this topic in [depth](#) should you wish to read into object literals further.

The Module Pattern

The Module pattern was initially defined to provide private and public encapsulation for classes in conventional software engineering.

At one point, organizing a JavaScript application of any reasonable size was a challenge. Developers would rely on separate scripts to split and manage reusable chunks of logic, and it wasn't surprising to find 10-20 scripts being imported manually in an HTML file to keep things tidy. Using objects, the module pattern was just one way to encapsulate logic in a file with both public and "private" methods. Over time, several custom module systems

came about to make this smoother. Now, developers can use JavaScript modules to organize objects, functions, classes, or variables such that they can be easily exported or imported into other files. This helps prevent conflicts between classes or function names included in different modules. The following figure illustrates the **module pattern**.

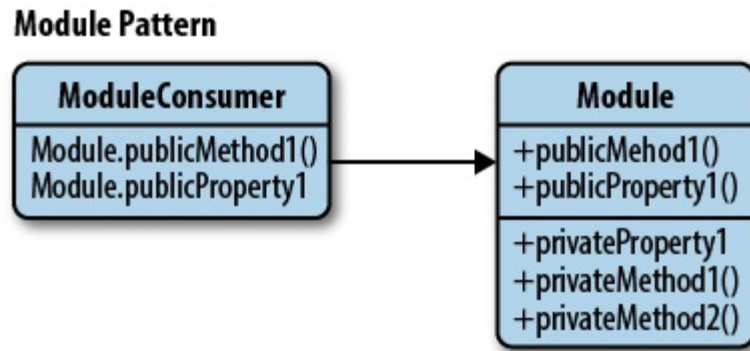

Figure 7-2. Module pattern

Privacy

The Module pattern encapsulates the “privacy” state and organization using closures. It provides a way of wrapping a mix of public and private methods and variables, protecting pieces from leaking into the global scope and accidentally colliding with another developer’s interface. With this pattern, you only expose the public API, keeping everything else within the closure private.

This gives us a clean solution where the shielding logic does the heavy lifting while we only expose an interface we wish other parts of our application to use. The pattern utilizes an immediately-invoked function expression¹ where an object is returned.

Note that there isn’t an explicitly true sense of “privacy” inside JavaScript because it doesn’t have access modifiers, unlike some traditional languages. You can’t technically declare variables as public or private, so we use function scope to simulate this concept. Within the Module pattern, variables or methods declared are only available inside the module itself, thanks to closure. However, variables or methods defined within the returning object are available to everyone.

A workaround to implement privacy of variables in returned objects uses `WeakMap()` discussed later in this chapter in Modern Module Pattern with `WeakMap`. `WeakMap()` only takes objects as keys and cannot be iterated. Thus, the only way to access the object inside a module is through its reference. Outside the module, you can only access it through a public method defined within it. Thus, it ensures privacy for the object.

History

From a historical perspective, the Module pattern was originally developed in 2003 by several people, including **Richard Cornford**. Douglas Crockford later popularized it in his lectures. Another piece of trivia is that some of its features may appear quite familiar if you've ever played with Yahoo's YUI library. The reason for this is that the Module pattern was a strong influence on YUI when creating its components.

Examples

Let's begin looking at implementing the Module pattern by creating a self-contained module. We use the `import` and `export` keywords in our implementation. To recap our previous discussion, `export` allows you to provide access to module features outside the module. At the same time, `import` enables us to import bindings exported by a module to our script.

```
let counter = 0;

const testModule = {
  incrementCounter() {
    return counter++;
  },
  resetCounter() {
    console.log(`counter value prior to reset:
${counter}`);
    counter = 0;
  },
};

// Default export module, without name
export default testModule;
```

```

// Usage:

// Import module from path
import testModule from './testModule';

// Increment our counter
testModule.incrementCounter();

// Check the counter value and reset
// Outputs: counter value prior to reset: 1
testModule.resetCounter();

```

Here, other parts of the code cannot directly read the value of our `incrementCounter()` or `resetCounter()`. The counter variable is entirely shielded from our global scope, so it acts just like a private variable would — its existence is limited to within the module's closure so that the two functions are the only code able to access its scope. Our methods are effectively namespaced, so in the test section of our code, we need to prefix any calls with the module's name (e.g., `testModule`).

When working with the Module pattern, we may find it helpful to define a simple template we can use to get started with it. Here's one that covers namespacing, public, and private variables:

```

// A private counter variable
let myPrivateVar = 0;

// A private function which logs any arguments
const myPrivateMethod = foo => {
  console.log(foo);
};

const myNamespace = {
  // A public variable
  myPublicVar: 'foo',

  // A public function utilizing privates
  myPublicFunction(bar) {
    // Increment our private counter

```

```

    myPrivateVar++;

    // Call our private method using bar
    myPrivateMethod(bar);
  },
};

export default myNamespace;

```

Looking at another example below, we can see a shopping basket implemented using this pattern. The module itself is completely self-contained in a global variable called `basketModule`. The `basket` array in the module is kept private, so other parts of our application cannot directly read it. It only exists within the module's closure, and so the only methods able to access it are those with access to its scope (i.e., `addItem()`, `getItem()`, etc.).

```

// privates

const basket = [];

const doSomethingPrivate = () => {
  //...
};

const doSomethingElsePrivate = () => {
  //...
};

// Create an object exposed to the public
const basketModule = {
  // Add items to our basket
  addItem(values) {
    basket.push(values);
  },

  // Get the count of items in the basket
  getItemCount() {
    return basket.length;
  },
};

```

```

    // Public alias to a private function
    doSomething() {
        doSomethingPrivate();
    },

    // Get the total value of items in the basket
    // The reduce() method applies a function against an
    accumulator and each
    // element in the array (from left to right) to reduce it
    to a single value.
    getTotal() {
        return basket.reduce((currentSum, item) => item.price +
currentSum, 0);
    },
};

export default basketModule;

```

Inside the module, you may have noticed that we return an object. This gets automatically assigned to `basketModule` so that we can interact with it as follows:

```

// Import module from path
import basketModule from './basketModule';

// basketModule returns an object with a public API we can
use

basketModule.addItem({
    item: 'bread',
    price: 0.5,
});

basketModule.addItem({
    item: 'butter',
    price: 0.3,
});

// Outputs: 2
console.log(basketModule.getItemCount());

```

```
// Outputs: 0.8
console.log(basketModule.getTotal());

// However, the following will not work:

// Outputs: undefined
// This is because the basket itself is not exposed as a
// part of our
// public API
console.log(basketModule.basket);

// This also won't work as it only exists within the scope
// of our
// basketModule closure, but not in the returned public
// object
console.log(basket);
```

The methods above are effectively namespaced inside `basketModule`. All our functions are wrapped in this module, giving us several advantages, such as:

- The freedom to have private functions that can only be consumed by our module. They aren't exposed to the rest of the page (only our exported API is), so they're considered truly private.
- Given that functions are usually declared and are named, it can be easier to show call stacks in a debugger when we're attempting to discover what function(s) threw an exception.
- As T.J. Crowder has pointed out in the past, it also enables us to return different functions depending on the environment. In the past, I've seen developers use this to perform UA testing to provide a code path in their module specific to IE, but we can easily opt for feature detection these days to achieve a similar goal.

Module Pattern Variations

Over time designers have introduced different variations of the module

pattern suited to their needs.

Import mixins

This pattern variation demonstrates how you can pass globals (e.g., jQuery, Underscore) as arguments to our module's anonymous function. This effectively allows us to *import* and locally alias them as we wish.

```
const privateMethod1 = () => {
  $(".container").html("test");
}

const privateMethod2 = () => {
  console.log(_.min([10, 5, 100, 2, 1000]));
}

const myModule = {
  publicMethod() {
    privateMethod1();
  }
};

// Default export module, without name
export default myModule;

// Import module from path
import myModule from './MyModule';

myModule.publicMethod();
```

Exports

This next variation allows us to declare globals without consuming them and could similarly support the concept of global imports seen in the last example.

```
// Module object
const module = {};
const privateVariable = 'Hello World';
```

```

const privateMethod = () => {
  // ...
};

module.publicProperty = 'Foobar';
module.publicMethod = () => {
  console.log(privateVariable);
};

// Default export module, without name
export default module;

```

Advantages

We've seen why the Constructor pattern can be useful, but why is the Module pattern a good choice? For starters, it's a lot cleaner for developers coming from an object-oriented background than the idea of true encapsulation, at least from a JavaScript perspective.

Secondly, it supports private data — so, in the Module pattern, we only have access to the values that we explicitly exported using the `export` keyword. Values we didn't expressly export are private and only available within the module. This reduces the risk of accidentally polluting the global scope. You don't have to fear that you will accidentally overwrite values created by developers using your module that may have had the same name as your private value: it prevents naming collisions and global scope pollution.

With the module pattern, we can encapsulate parts of our code that should not be publicly exposed. They make working with multiple dependencies and namespaces less risky. Note that a transpiler such as Babel is needed to use ES2015 modules in all JavaScript runtimes.

Disadvantages

The disadvantages of the Module pattern are that we access both public and private members differently. When we wish to change the visibility, we must make changes to each place we use the member.

We also can't access private members in methods we added to the object later. That said, in many cases, the Module pattern is still quite helpful and,

when used correctly, certainly has the potential to improve the structure of our application.

Other disadvantages include the inability to create automated unit tests for private members and additional complexity when bugs require hot fixes. It's simply not possible to patch privates. Instead, one must override all public methods interacting with the buggy privates. Developers can't easily extend privates either, so it's worth remembering privates are not as flexible as they may initially appear.

For further reading on the Module pattern, see Ben Cherry's excellent in-depth [article](#).

Modern Module Pattern with WeakMap

Introduced to JavaScript in ES6, the **WeakMap** object is a collection of key/value pairs in which the keys are weakly referenced. The keys must be objects, and the values can be arbitrary. The object is essentially a map where keys are held weakly. This means that keys will be a target for garbage collection (GC) if there is no active reference to the object. Let us look at an implementation of the module pattern that uses the WeakMap object.

Example 7-2. Basic Module Definition

```
let _counter = new WeakMap();

class Module {
  constructor() {
    _counter.set(this, 0);
  }
  incrementCounter() {
    let counter = _counter.get(this);
    counter++;
    _counter.set(this, counter);

    return _counter.get(this);
  }
  resetCounter() {
    console.log(`counter value prior to reset:
    ${_counter.get(this)}`);
```

```

        _counter.set(this, 0);
    }
}

const testModule = new Module();

// Usage:

// Increment our counter
testModule.incrementCounter();
// Check the counter value and reset
// Outputs: counter value prior to reset: 1
testModule.resetCounter();

```

Example 7-3. Namespaces with Public/Private variables

```

const myPrivateVar = new WeakMap();
const myPrivateMethod = new WeakMap();

class MyNamespace {
  constructor() {
    // A private counter variable
    myPrivateVar.set(this, 0);
    // A private function which logs any arguments
    myPrivateMethod.set(this, foo => console.log(foo));
    // A public variable
    this.myPublicVar = 'foo';
  }
  // A public function utilizing privates
  myPublicFunction(bar) {
    let privateVar = myPrivateVar.get(this);
    const privateMethod = myPrivateMethod.get(this);
    // Increment our private counter
    privateVar++;
    myPrivateVar.set(this, privateVar);
    // Call our private method using bar
    privateMethod(bar);
  }
}

```

Example 7-4. Shopping Basket Implementation

```

const basket = new WeakMap();
const doSomethingPrivate = new WeakMap();

```

```

const doSomethingElsePrivate = new WeakMap();

class BasketModule {
  constructor() {
    // privates
    basket.set(this, []);
    doSomethingPrivate.set(this, () => {
      //...
    });
    doSomethingElsePrivate.set(this, () => {
      //...
    });
  }
  // Public aliases to a private functions
  doSomething() {
    doSomethingPrivate.get(this)();
  }
  doSomethingElse() {
    doSomethingElsePrivate.get(this)();
  }
  // Add items to our basket
  addItem(values) {
    const basketData = basket.get(this);
    basketData.push(values);
    basket.set(this, basketData);
  }
  // Get the count of items in the basket
  getItemCount() {
    return basket.get(this).length;
  }
  // Get the total value of items in the basket
  getTotal() {
    return basket
      .get(this)
      .reduce((currentSum, item) => item.price +
currentSum, 0);
  }
}

```

Modules with modern libraries

You can use the Module pattern when building applications with JavaScript

libraries such as React. Let's say you have a large number of custom components created by your team. In that case, you can separate each component in its own file, essentially creating a module for every component. Here is an example of a button component customized from the **material-ui** button component and exported as a module.

```
import React from "react";
import Button from "@material-ui/core/Button";

const style = {
  root: {
    borderRadius: 3,
    border: 0,
    color: "white",
    margin: "0 20px"
  },
  primary: {
    background: "linear-gradient(45deg, #FE6B8B 30%,
#FF8E53 90%)"
  },
  secondary: {
    background: "linear-gradient(45deg, #2196f3 30%,
#21cbf3 90%)"
  }
};

export default function CustomButton(props) {
  return (
    <Button {...props} style={{ ...style.root,
...style[props.color] }}>
      {props.children}
    </Button>
  );
}
```

The Revealing Module Pattern

Now that we are a little more familiar with the Module pattern let's look at a slightly improved version — Christian Heilmann's Revealing Module

pattern.

The Revealing Module pattern came about as Heilmann was frustrated that he had to repeat the name of the main object when he wanted to call one public method from another or access public variables. He also disliked switching to object literal notation for the things he wished to make public.

His efforts resulted in an updated pattern where we can simply define all functions and variables in the private scope and return an anonymous object with pointers to the private functionality we wished to reveal as public.

With the modern way of implementing **modules** in ES2015+, the scope of functions and variables defined in the module is already private. Also, we use **export** and **import** to reveal whatever needs to be revealed.

An example of the use of the Revealing Module pattern with ES2015+ is as follows:

```
let privateVar = 'Ben Cherry';
const publicVar = 'Hey there!';

const privateFunction = () => {
  console.log(`Name:${privateVar}`);
};

const publicSetName = strName => {
  privateVar = strName;
};

const publicGetName = () => {
  privateFunction();
};

// Reveal public pointers to
// private functions and properties
const myRevealingModule = {
  setName: publicSetName,
  greeting: publicVar,
  getName: publicGetName,
};
```

```

export default myRevealingModule;

// Usage:
import myRevealingModule from './myRevealingModule';

myRevealingModule.setName('Paul Kinlan');

```

In the above example, we reveal the private variable `privateVar` through its public get and set methods, `publicSetName`, and `publicGetName`.

You can also use the pattern to reveal private functions and properties with a more specific naming scheme.

```

let privateCounter = 0;

const privateFunction = () => {
  privateCounter++;
}

const publicFunction = () => {
  publicIncrement();
}

const publicIncrement = () => {
  privateFunction();
}

const publicGetCount = () => privateCounter;

// Reveal public pointers to
// private functions and properties
const myRevealingModule = {
  start: publicFunction,
  increment: publicIncrement,
  count: publicGetCount
};

export default myRevealingModule;

// Usage:
import myRevealingModule from './myRevealingModule';

```

```
myRevealingModule.start();
```

Advantages

This pattern allows the syntax of our scripts to be more consistent. It also makes it easier to understand at the end of the module which of our functions and variables may be accessed publicly, which eases readability.

Disadvantages

A disadvantage of this pattern is that if a private function refers to a public function, that public function can't be overridden if a patch is necessary. This is because the private function will continue to refer to the private implementation, and the pattern doesn't apply to public members, only to functions.

Public object members, which refer to private variables, are also subject to the no-patch rule.

As a result, modules created with the Revealing Module pattern may be more fragile than those created with the original Module pattern, and you should take care when using it.

The Singleton Pattern

The Singleton pattern is a design pattern that restricts the instantiation of a class to one object. This is useful when exactly one object is needed to coordinate actions across the system. Classically, you can implement the Singleton pattern by creating a class with a method that creates a new instance of the class only if one doesn't already exist. If an instance already exists, it simply returns a reference to that object.

Singletons differ from static classes (or objects) as we can delay their initialization because they require certain information that may not be available during initialization time. Any code that is unaware of a previous reference to the Singleton class cannot easily retrieve it. This is because it is

neither the object nor “class” that a Singleton returns; it’s a structure. Think of how closed variables aren’t actually closures—the function scope that provides the closure is the closure.

ES2015+ allows us to implement the singleton pattern to create a global instance of a JavaScript class that is instantiated once. You can expose the singleton instance through a module export. This makes access to it more explicit and controlled and differentiates it from other global variables. You cannot create a new class instance but can read/modify the instance using public get and set methods defined in the class.

We can implement a Singleton as follows:

```
// Instance stores a reference to the Singleton
let instance;

// Private methods and variables
const privateMethod = () => {
  console.log('I am private');
};
const privateVariable = 'Im also private';
const randomNumber = Math.random();

// Singleton
class MySingleton {
  // Get the Singleton instance if one exists
  // or create one if it doesn't
  constructor() {
    if (!instance) {
      // Public property
      this.publicProperty = 'I am also public';
      instance = this;
    }

    return instance;
  }

  // Public methods
  publicMethod() {
    console.log('The public can see me!');
  }
}
```

```

    getRandomNumber() {
        return randomNumber;
    }
}
// [ES2015+] Default export module, without name
export default MySingleton;

```

```

// Instance stores a reference to the Singleton
let instance;

```

```

// Singleton
class MyBadSingleton {
    // Always create a new Singleton instance
    constructor() {
        this.randomNumber = Math.random();
        instance = this;

        return instance;
    }

    getRandomNumber() {
        return this.randomNumber;
    }
}

```

```

export default MyBadSingleton;

```

```

// Usage:
import MySingleton from './MySingleton';
import MyBadSingleton from './MyBadSingleton';

```

```

const singleA = new MySingleton();
const singleB = new MySingleton();
console.log(singleA.getRandomNumber() ===
singleB.getRandomNumber());
// true

```

```

const badSingleA = new MyBadSingleton();
const badSingleB = new MyBadSingleton();
console.log(badSingleA.getRandomNumber() !==

```

```

badSingleB.getRandomNumber());
// true

// Note: as we are working with random numbers, there is a
// mathematical
// possibility both numbers will be the same, however
// unlikely.
// The above example should otherwise still be valid.

```

What makes the Singleton is the global access to the instance. The GoF book describes the *applicability* of the Singleton pattern as follows:

- There must be exactly one instance of a class, and it must be accessible to clients from a well-known access point.
- The sole instance should be extensible by subclassing, and clients should be able to use an extended instance without modifying their code.

The second of these points refers to a case where we might need code, such as:

```

constructor() {
    if (this._instance == null) {
        if (isFoo()) {
            this._instance = new FooSingleton();
        } else {
            this._instance = new BasicSingleton();
        }
    }

    return this._instance;
}

```

Here, the `constructor` becomes a little like a Factory method, and we don't need to update each point in our code accessing it. `FooSingleton` (above) would be a subclass of `BasicSingleton` and implement the same interface.

Why is deferring execution considered significant for a Singleton? In C++, it serves as isolation from the unpredictability of the dynamic initialization

order, returning control to the programmer.

It is essential to note the difference between a static instance of a class (object) and a Singleton. While you can implement a Singleton as a static instance, it can also be constructed lazily, without the need for resources or memory until it is needed.

Suppose we have a static object that we can initialize directly. In that case, we need to ensure the code is always executed in the same order (e.g., in case `objCar` needs `objWheel` during its initialization), and this doesn't scale when you have a large number of source files.

Both Singletons and static objects are useful but shouldn't be overused—the same way we shouldn't overuse other patterns.

In practice, it helps to use the Singleton pattern when exactly one object is needed to coordinate others across a system. Here is one example that uses the pattern in this context:

```
// options: an object containing configuration options for
// the singleton
// e.g const options = { name: "test", pointX: 5};
class Singleton {
  constructor(options = {}) {
    // set some properties for our singleton
    this.name = 'SingletonTester';
    this.pointX = options.pointX || 6;
    this.pointY = options.pointY || 10;
  }
}

// our instance holder
let instance;

// an emulation of static variables and methods
const SingletonTester = {
  name: 'SingletonTester',
  // Method for getting an instance. It returns
  // a singleton instance of a singleton object
  getInstance(options) {
    if (instance === undefined) {
```

```

        instance = new Singleton(options);
    }

    return instance;
},
};

const singletonTest = SingletonTester.getInstance({
    pointX: 5,
});

// Log the output of pointX just to verify it is correct
// Outputs: 5
console.log(singletonTest.pointX);

```

While the Singleton has valid uses, often, when we find ourselves needing it in JavaScript, it's a sign that we may need to re-evaluate our design. Unlike C++ or Java, where you have to define a class to create an object, JavaScript allows you to create objects directly. Thus, you can create one such object directly instead of defining a singleton class. In contrast, using singleton classes in JavaScript has some disadvantages.

Identifying Singletons can be difficult

If you are importing a large module, you will be unable to recognize that a particular class is a Singleton. As a result, you may accidentally use it as a regular class to instantiate multiple objects and incorrectly update it instead.

Challenging to test

Singletons can be more difficult to test due to issues ranging from hidden dependencies, difficulty creating multiple instances, difficulty in stubbing dependencies, and so on.

Need for careful orchestration

An everyday use case for Singletons would be to store data that will be required across the global scope, such as user credentials or cookie data that can be set once and consumed by multiple components.

Implementing the correct execution order becomes essential so that data is always consumed after it becomes available and not the other way around. This may become challenging as the application grows in size and complexity.

Miller Medeiros has previously recommended this excellent [article](#) on the Singleton and its various issues for further reading, and the comments to this [article](#) discuss how Singletons can increase tight coupling. I'm happy to second these recommendations as both pieces raise many important points about this pattern that are also worth noting.

State management in React

Developers using React for web development can rely on the global state through state management tools such as Redux or React Context instead of Singletons. Unlike Singletons, these tools provide a read-only state rather than the mutable state.

Although the downsides to having a global state don't magically disappear by using these tools, we can at least ensure that the global state is mutated the way we intend it to since components cannot update it directly.

The Prototype Pattern

The GoF refers to the Prototype pattern as one that creates objects based on a template of an existing object through cloning.

We can think of the Prototype pattern as being based on prototypal inheritance, where we create objects which act as prototypes for other objects. The `prototype` object is effectively used as a blueprint for each object the constructor creates. For example, if the prototype of the constructor function used contains a property called `name` (as per the code sample that follows), then each object created by that constructor will also have this same property. Refer [Figure 7-3](#) for an illustration.

Prototype Pattern

Figure 7-3. Prototype pattern

Reviewing the definitions for this pattern in existing (non-JavaScript) literature, we *may* find references to classes once again. The reality is that prototypal inheritance avoids using classes altogether. There isn't a "definition" object nor a core object in theory; we're simply creating copies of existing functional objects.

One of the benefits of using the Prototype pattern is that we're working with the prototypal strengths JavaScript has to offer natively rather than attempting to imitate features of other languages. With other design patterns, this isn't always the case.

Not only is the pattern an easy way to implement inheritance, but it can also come with a performance boost. When defining functions in an object, they're all created by reference (so all child objects point to the same functions), instead of creating individual copies.

With ES2015+, we can use classes and constructors to create objects. While this ensures that our code looks cleaner and follows OOAD principles, the classes and constructors get compiled down to functions and prototypes internally. This ensures that we are still working with the prototypal strengths of JavaScript and the accompanying performance boost.

For those interested, real prototypal inheritance, as defined in the ECMAScript 5 standard, requires the use of `Object.create` (which we

previously looked at earlier in this section). To review, `Object.create` creates an object with a specified prototype and optionally contains specified properties (e.g., `Object.create(prototype, optionalDescriptorObjects)`).

We can see this demonstrated in the following example:

```
const myCar = {
  name: 'Ford Escort',

  drive() {
    console.log("Weeee. I'm driving!");
  },

  panic() {
    console.log('Wait. How do you stop this thing?');
  },
};

// Use Object.create to instantiate a new car
const yourCar = Object.create(myCar);

// Now we can see that one is a prototype of the other
console.log(yourCar.name);
```

`Object.create` also allows us to easily implement advanced concepts such as differential inheritance, where objects are able to directly inherit from other objects. We saw earlier that `Object.create` allows us to initialize object properties using the second supplied argument. For example:

```
const vehicle = {
  getModel() {
    console.log(`The model of this vehicle
is..${this.model}`);
  },
};

const car = Object.create(vehicle, {
  id: {
    value: MY_GLOBAL.nextId(),
```

```

        // writable:false, configurable:false by default
        enumerable: true,
    },

    model: {
        value: 'Ford',
        enumerable: true,
    },
});

```

Here, you can initialize the properties on the second argument of `Object.create` using an object literal with a syntax similar to that used by the `Object.defineProperties` and `Object.defineProperty` methods that we looked at previously.

It is worth noting that prototypal relationships can cause trouble when enumerating properties of objects and (as Crockford recommends) wrapping the contents of the loop in a `hasOwnProperty()` check.

If we wish to implement the Prototype pattern without directly using `Object.create`, we can simulate the pattern as per the above example as follows:

```

class VehiclePrototype {
    constructor(model) {
        this.model = model;
    }

    getModel() {
        console.log('The model of this vehicle is..' +
this.model);
    }

    Clone() {}
}

class Vehicle extends VehiclePrototype {
    constructor(model) {
        super(model);
    }
    Clone() {

```

```

        return new Vehicle(this.model);
    }
}

const car = new Vehicle('Ford Escort');
const car2 = car.Clone();
car2.getModel();

```

NOTE

This alternative does not allow the user to define read-only properties in the same manner (as the `vehiclePrototype` may be altered if not careful).

A final alternative implementation of the Prototype pattern could be the following:

```

const beget = (() => {
    class F {
        constructor() {}
    }

    return proto => {
        F.prototype = proto;
        return new F();
    };
})();

```

One could reference this method from the `vehicle` function. However, note that `vehicle` here emulates a constructor since the Prototype pattern does not include any notion of initialization beyond linking an object to a prototype.

The Factory Pattern

The Factory pattern is another creational pattern for creating objects. It differs from the other patterns in its category because it doesn't explicitly require us

to use a constructor. Instead, a Factory can provide a generic interface for creating objects, where we can specify the type of factory object we want to create(Figure 7-4).

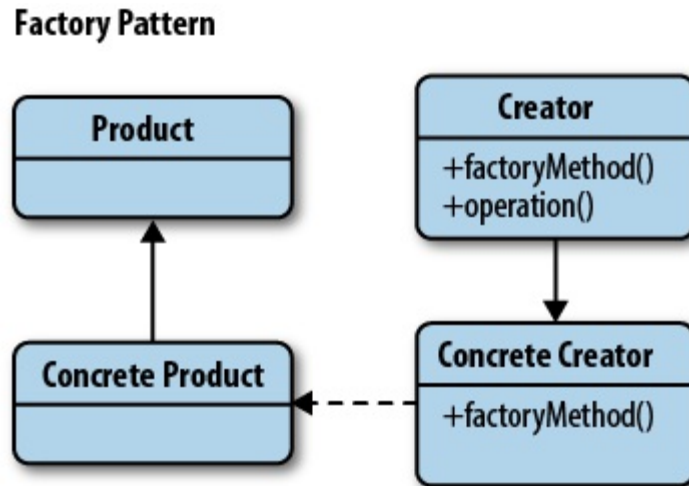

Figure 7-4. Factory pattern

Imagine a UI factory where we want to create a type of UI component. Rather than creating this component directly using the `new` operator or another creational constructor, we ask a Factory object for a new component instead. We inform the Factory what type of object is required (e.g., “Button”, “Panel”), and it instantiates it and returns it to us for use.

This is particularly useful if the object creation process is relatively complex, e.g., if it strongly depends on dynamic factors or application configuration.

You can find examples of this pattern in UI libraries such as ExtJS, where the methods for creating objects or components may be further subclassed.

The following example builds upon our previous snippets using the Constructor pattern logic to define cars. It demonstrates how a `VehicleFactory` may be implemented using the Factory pattern:

```
// Types.js - Constructors used behind the scenes

// A constructor for defining new cars
class Car {
  constructor({
    doors,
```

```

        state,
        color
    }) {
        // some defaults
        this.doors = doors || 4;
        this.state = state || 'brand new';
        this.color = color || 'silver';
    }
}
// A constructor for defining new trucks
class Truck {
    constructor({
        state,
        wheelSize,
        color
    }) {
        this.state = state || 'used';
        this.wheelSize = wheelSize || 'large';
        this.color = color || 'blue';
    }
}

// FactoryExample.js

// Define a vehicle factory
class VehicleFactory {
    // Define the prototypes and utilities for this factory

    // Our default vehicleClass is Car
    constructor() {
        this.vehicleClass = Car;
    }
    // Our Factory method for creating new Vehicle
    instances
    createVehicle(options) {
        switch (options.vehicleType) {
            case 'car':
                this.vehicleClass = Car;
                break;
            case 'truck':
                this.vehicleClass = Truck;
                break;
            //defaults to

```

```

VehicleFactory.prototype.vehicleClass (Car)
    }

    return new this.vehicleClass(options);
}
}

// Create an instance of our factory that makes cars
const carFactory = new VehicleFactory();
const car = carFactory.createVehicle({
  vehicleType: 'car',
  color: 'yellow',
  doors: 6,
});

// Test to confirm our car was created using the
vehicleClass/prototype Car

// Outputs: true
console.log(car instanceof Car);

// Outputs: Car object of color "yellow", doors: 6 in a
"brand new" state
console.log(car);

```

We have defined the car and truck classes with constructors that set properties relevant to the respective vehicle. The `VehicleFactory` can create a new vehicle object, `Car`, or `Truck` based on the `vehicleType` passed.

There are two possible approaches to building trucks using the `VehicleFactory` class.

In Approach 1, we modify a `VehicleFactory` instance to use the `Truck` class:

```

const movingTruck = carFactory.createVehicle({
  vehicleType: 'truck',
  state: 'like new',
  color: 'red',
  wheelSize: 'small',

```

```
});

// Test to confirm our truck was created with the
vehicleClass/prototype Truck

// Outputs: true
console.log(movingTruck instanceof Truck);

// Outputs: Truck object of color "red", a "like new" state
// and a "small" wheelSize
console.log(movingTruck);
```

In Approach 2, we subclass `VehicleFactory` to create a factory class that builds Trucks:

```
class TruckFactory extends VehicleFactory {
  constructor() {
    super();
    this.vehicleClass = Truck;
  }
}
const truckFactory = new TruckFactory();
const myBigTruck = truckFactory.createVehicle({
  state: 'omg..so bad.',
  color: 'pink',
  wheelSize: 'so big',
});

// Confirms that myBigTruck was created with the prototype
Truck
// Outputs: true
console.log(myBigTruck instanceof Truck);

// Outputs: Truck object with the color "pink", wheelSize
"so big"
// and state "omg. so bad"
console.log(myBigTruck);
```

When to Use the Factory Pattern

The Factory pattern can be beneficial when applied to the following

situations:

- When our object or component setup involves a high level of complexity
- When we need a convenient way to generate different instances of objects depending on the environment, we are in
- When we're working with many small objects or components that share the same properties
- When composing objects with instances of other objects that need only satisfy an API contract (aka, duck typing) to work. This is useful for decoupling.

When Not to Use the Factory Pattern

When applied to the wrong type of problem, this pattern can introduce a large amount of unnecessary complexity to an application. Unless providing an interface for object creation is a design goal for the library or framework we are writing, I would suggest sticking to explicit constructors to avoid undue overhead.

Since the process of object creation is effectively abstracted behind an interface, this can also introduce problems with unit testing, depending on just how complex this process might be.

Abstract Factories

It is also worthwhile to be aware of the Abstract Factory pattern, which aims to encapsulate a group of individual factories with a common goal. It separates the details of implementing a set of objects from their general usage.

You can use an Abstract Factory when a system must be independent of how the objects it creates are generated, or it needs to work with multiple types of objects.

An example that is both simple and easier to understand is a vehicle factory,

which defines ways to get or register vehicle types. The abstract factory can be named `AbstractVehicleFactory`. The Abstract factory will allow the definition of types of vehicles like `car` or `truck`, and concrete factories will implement only classes that fulfill the vehicle contract (e.g., `Vehicle.prototype.drive` and `Vehicle.prototype.breakDown`).

```
class AbstractVehicleFactory {
  constructor() {
    // Storage for our vehicle types
    this.types = {};
  }

  static getVehicle(type, customizations) {
    const Vehicle = this.types[type];

    return Vehicle ? new Vehicle(customizations) :
null;
  }

  static registerVehicle(type, Vehicle) {
    const proto = Vehicle.prototype;

    // only register classes that fulfill the vehicle
contract
    if (proto.drive && proto.breakDown) {
      this.types[type] = Vehicle;
    }

    return abstractVehicleFactory;
  }
}

// Usage:

abstractVehicleFactory.registerVehicle('car', Car);
abstractVehicleFactory.registerVehicle('truck', Truck);

// Instantiate a new car based on the abstract vehicle type
const car = abstractVehicleFactory.getVehicle('car', {
  color: 'lime green',
```

```
        state: 'like new',
    });

    // Instantiate a new truck in a similar manner
    const truck = abstractVehicleFactory.getVehicle('truck', {
        wheelSize: 'medium',
        color: 'neon yellow',
    });
```

Structural Patterns

Structural patterns deal with class and object composition. For example, the concept of inheritance allows us to compose interfaces and objects so that they can obtain new functionality. Structural patterns provide the best methods and practices to organize classes and objects.

Following are the JavaScript structural patterns that we will discuss in this section.

- “The Facade Pattern”
- “The Mixin Pattern”
- “The Decorator Pattern”
- “Flyweight”

The Facade Pattern

When we put up a facade, we present an outward appearance to the world, which may conceal a very different reality. This inspired the name for the next pattern we’ll review—the Facade pattern. This pattern provides a convenient higher-level interface to a larger body of code, hiding its true underlying complexity. Think of it as simplifying the API being presented to other developers, a quality that almost always improves usability (Figure 7-5).

Facade Pattern

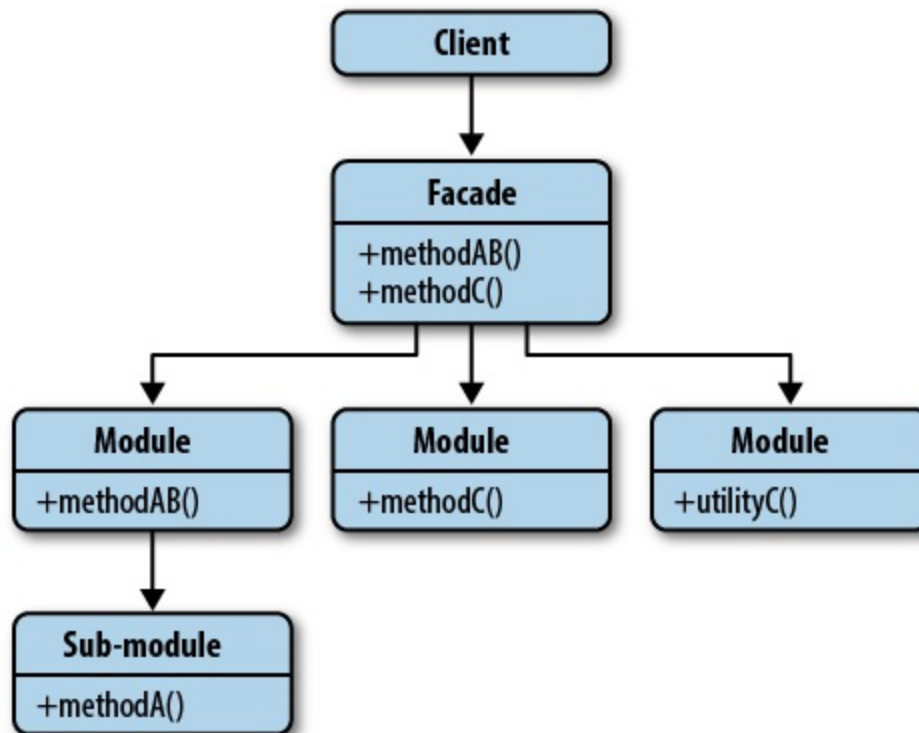

Figure 7-5. Facade pattern

Facades are a structural pattern that can often be seen in JavaScript libraries such as jQuery where, although an implementation may support methods with a wide range of behaviors, only a “facade,” or limited abstraction of these methods, is presented to the public for use.

This allows us to interact with the Facade directly rather than the subsystem behind the scenes. Whenever we use jQuery’s `$(el).css()` or `$(el).animate()` methods, we’re using a Facade: the simpler public interface that lets us avoid manually calling the many internal methods in jQuery core required to get some behavior working. This also circumvents the need to interact manually with DOM APIs and maintain state variables.

The jQuery core methods should be considered intermediate abstractions. The more immediate burden to developers is that the DOM API and facades make the jQuery library so easy to use.

To build on what we’ve learned, the Facade pattern simplifies a class’s interface and decouples the class from the code that utilizes it. This allows us

to interact indirectly with subsystems in a way that can sometimes be less error-prone than accessing the subsystem directly. A Facade's advantages include ease of use and often a small-sized footprint in implementing the pattern.

Let's take a look at the pattern in action. This is an unoptimized code example, but here we're using a Facade to simplify an interface for listening to events across browsers. We do this by creating a common method that does the task of checking for the existence of features so that it can provide a safe and cross-browser-compatible solution.

```
const addMyEvent = (el, ev, fn) => {  
  if (el.addEventListener) {  
    el.addEventListener(ev, fn, false);  
  } else if (el.attachEvent) {  
    el.attachEvent(`on${ev}`, fn);  
  } else {  
    el[`on${ev}`] = fn;  
  }  
};
```

In a similar manner, we're all familiar with jQuery's `$(document).ready(. .)`. Internally, this is powered by a method called `bindReady()`, which is doing this:

```
function bindReady() {  
  // ...  
  if (document.addEventListener) {  
    // Use the handy event callback  
    document.addEventListener('DOMContentLoaded',  
    DOMContentLoaded, false);  
  
    // A fallback to window.onload, that will always  
    work  
    window.addEventListener('load', jQuery.ready,  
    false);  
  
    // If IE event model is used  
  } else if (document.attachEvent) {
```

```

        document.attachEvent('onreadystatechange',
DOMContentLoaded);

        // A fallback to window.onload, that will always
work
        window.attachEvent('onload', jQuery.ready);
    }
}

```

This is another example of a Facade where the rest of the world uses the limited interface exposed by `$(document).ready(. .)`, and the more complex implementation powering it is kept hidden from sight.

Facades don't just have to be used on their own, however. You can also integrate them with other patterns, such as the Module pattern. As we can see below, our instance of the Module pattern contains a number of methods that have been privately defined. A Facade is then used to supply a much simpler API for accessing these methods:

```

const _private = {
  i: 5,
  get() {
    console.log(`current value:${this.i}`);
  },
  set(val) {
    this.i = val;
  },
  run() {
    console.log('running');
  },
  jump() {
    console.log('jumping');
  },
};

```

```

// We used the destructuring assignment syntax that makes
it possible to
// unpack values from data structures into distinct
variables.

```

```

const module = {
  facade({ val, run }) {
    _private.set(val);
    _private.get();
    if (run) {
      _private.run();
    }
  },
};

export default module;

import module from './module.js';
// Outputs: "current value: 10" and "running"
module.facade({
  run: true,
  val: 10,
});

```

In this example, calling `module.facade()` will trigger a set of private behavior within the module, but the users aren't concerned with this. We've made it much easier for them to consume a feature without worrying about implementation-level details.

Notes on Abstraction

Facades generally have a few disadvantages, but one concern worth noting is performance. Namely, one must determine whether there is an implicit cost to the abstraction a Facade offers to our implementation and whether this cost is justifiable. Going back to the jQuery library, most of us are aware that both `getElementById("identifier")` and `$("#identifier")` can be used to query an element on a page by its ID.

Did you know, however, that `getElementById()` on its own is significantly faster by a high order of magnitude? Take a look at this [jsPerf](#) test to see results on a per-browser level. Of course, we have to keep in mind that jQuery (and Sizzle, its selector engine) are doing a lot more behind the scenes to optimize our query (and that a jQuery object, not just a DOM node,

is returned).

The challenge with this particular Facade is that in order to provide an elegant selector function capable of accepting and parsing multiple types of queries, there is an implicit cost of abstraction. The user isn't required to access `jQuery.getById("identifier")` or `jQuery.getByClass("identifier")` and so on. That said, the trade-off in performance has been tested in practice over the years, and given the success of jQuery in the past, a simple Facade worked out very well for the team.

When using the Facade pattern, try to be aware of any performance costs involved and decide whether they are worth the level of abstraction offered.

The Mixin Pattern

In traditional programming languages such as C++ and Lisp, Mixins are classes that offer functionality that a sub-class or group of sub-classes can easily inherit for function re-use.

Subclassing

We have already introduced the ES2015+ features that allow us to extend a base or superclass and call the methods in the superclass. The child class that extends the superclass is known as a sub-class.

Sub-classing refers to inheriting properties for a new object from a base or superclass object. A sub-class can still define its methods, including those that override methods initially defined in the superclass. The method in the sub-class can invoke an overridden method in the superclass, known as method chaining. Similarly, it can invoke the superclass's constructor, which is known as constructor chaining.

To demonstrate sub-classing, we first need a base class that can have new instances of itself created. Let's model this around the concept of a person.

```

class Person{
  constructor(firstName, lastName) {
    this.firstName = firstName;
    this.lastName = lastName;
    this.gender = "male";
  }
}
// a new instance of Person can then easily be created as follows:
const clark = new Person( 'Clark', 'Kent' );

```

Next, we'll want to specify a new class that's a subclass of the existing `Person` class. Let us imagine we want to add distinct properties to distinguish a `Person` from a `Superhero` while inheriting the properties of the `Person` superclass. As superheroes share many common traits with ordinary people (e.g., name, gender), this should hopefully illustrate how subclassing works adequately.

```

class Superhero extends Person {
  constructor(firstName, lastName, powers) {
    // Invoke the superclass constructor
    super(firstName, lastName);
    this.powers = powers;
  }
}

// A new instance of Superhero can be created as follows

const SuperMan = new Superhero('Clark', 'Kent',
  ['flight', 'heat-vision']);
console.log(SuperMan);

// Outputs Person attributes as well as power

```

The `Superhero` constructor creates an instance of the `Superhero` class, which is an extension of the `Person` class. Objects of this type have attributes of the classes above it in the chain. If we had set default values in the `Person` class, `Superhero` could override any inherited values with values specific to its class.

Mixins

In JavaScript, we can look at inheriting from Mixins to collect functionality through extension. Each new class we define can have a superclass from which it can inherit methods and properties. Classes can also define their own properties and methods. We can leverage this fact to promote function reuse(Figure 7-6).

Figure 7-6. Mixins

Mixins allow objects to borrow (or inherit) functionality from them with minimal complexity. Thus, Mixins are classes with attributes and methods that can be easily shared across several other classes.

While JavaScript classes cannot inherit from multiple superclasses, we can still mix functionality from various classes. A class in JavaScript can be used as an expression as well as a statement. As an expression, it returns a new class each time it's evaluated. The extends clause can also accept arbitrary expressions that return classes or constructors. These features enable us to define a mixin as a function that accepts a superclass and creates a new subclass from it.

Imagine that we define a Mixin containing utility functions in a standard JavaScript class as follows:

```
const MyMixins = superclass =>
  class extends superclass {
```

```

        moveUp() {
            console.log('move up');
        }
        moveDown() {
            console.log('move down');
        }
        stop() {
            console.log('stop! in the name of love!');
        }
    };

```

Above, we created a MyMixins function that can extend a dynamic superclass. We will now create two classes, CarAnimator and PersonAnimator, from which MyMixins can extend and return a sub-class with methods defined in MyMixins and those in the class being extended.

```

// A skeleton carAnimator constructor
class CarAnimator {
    moveLeft() {
        console.log('move left');
    }
}
// A skeleton personAnimator constructor
class PersonAnimator {
    moveRandomly() {
        /*...*/
    }
}

// Extend MyMixins using CarAnimator
class MyAnimator extends MyMixins(CarAnimator) {}

// Create a new instance of carAnimator
const myAnimator = new MyAnimator();
myAnimator.moveLeft();
myAnimator.moveDown();
myAnimator.stop();

// Outputs:
// move left
// move down

```

```
// stop! in the name of love!
```

As we can see, this makes mixing similar behaviour into classes reasonably trivial.

The following example has two classes: a `Car` and a `Mixin`. What we're going to do is augment (another way of saying extend) the `Car` so that it can inherit specific methods defined in the `Mixin`, namely `driveForward()` and `driveBackward()`.

This example will demonstrate how to augment a constructor to include functionality without the need to duplicate this process for every constructor function we may have.

```
// Define a simple Car constructor
class Car {
  constructor({ model, color }) {
    this.model = model || 'no model provided';
    this.color = color || 'no colour provided';
  }
}

// Mixin
const Mixin = superclass =>
  class extends superclass {
    driveForward() {
      console.log('drive forward');
    }
    driveBackward() {
      console.log('drive backward');
    }
    driveSideways() {
      console.log('drive sideways');
    }
  };

class MyCar extends Mixin(Car) {}

// Create a new Car
const myCar = new MyCar({
  model: 'Ford Escort',
```

```

        color: 'blue',
    });

    // Test to make sure we now have access to the methods
    myCar.driveForward();
    myCar.driveBackward();

    // Outputs:
    // drive forward
    // drive backward

    const mySportCar = new MyCar({
        model: 'Porsche',
        color: 'red',
    });

    mySportsCar.driveSideways();

    // Outputs:
    // drive sideways

```

Advantages & Disadvantages

Mixins assist in decreasing functional repetition and increasing function reuse in a system. Where an application is likely to require shared behavior across object instances, we can easily avoid duplication by maintaining this shared functionality in a Mixin and thus focusing on implementing only the functionality in our system, which is truly distinct.

That said, the downsides to Mixins are a little more debatable. Some developers feel that injecting functionality into a class or an object prototype is a bad idea as it leads to both prototype pollution and a level of uncertainty regarding the origin of our functions. In large systems, this may well be the case.

Even with React, Mixins were often used to add functionality to components before the introduction of ES6 classes. The React team **discourages mixins** as it adds unnecessary complexity to a component, making it hard to maintain and reuse. The React team **encouraged using higher order components and**

Hooks instead.

I would argue that solid documentation can assist in minimizing the amount of confusion regarding the source of mixed-in functions. Still, as with every pattern, we should be okay if we take care during implementation.

The Decorator Pattern

Decorators are a structural design pattern that aims to promote code reuse. Like Mixins, you can think of them as another viable alternative to object sub-classing.

Classically, Decorators offered the ability to add behavior to existing classes in a system dynamically. The idea was that the *decoration* itself wasn't essential to the base functionality of the class. Otherwise, we could bake it into the *superclass* itself.

We can use them to modify existing systems where we wish to add additional features to objects without heavily changing the underlying code that uses them. A common reason developers use them is that their applications may contain features requiring many distinct types of objects. Imagine defining hundreds of different object constructors for, say, a JavaScript game (Figure 7-7).

Decorator Pattern

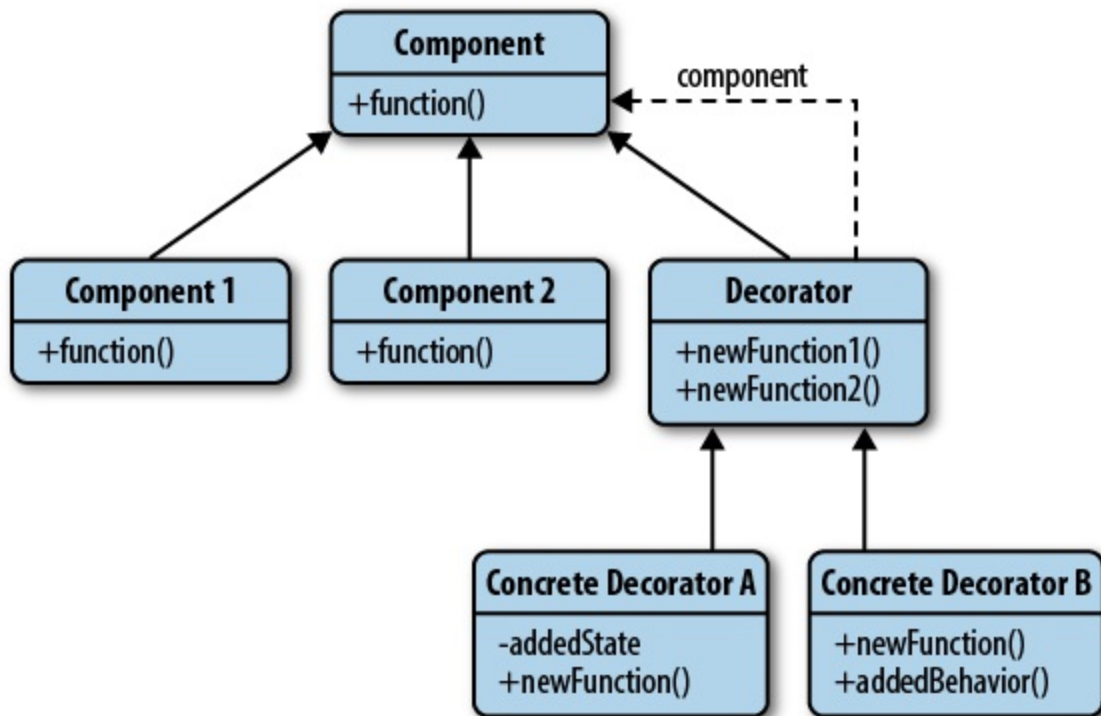

Figure 7-7. Decorator pattern

The object constructors could represent distinct player types, each with differing capabilities. A *Lord of the Rings* game could require constructors for Hobbit, Elf, Orc, Wizard, Mountain Giant, Stone Giant, and so on, but there could easily be hundreds of these. If we then factored in capabilities, imagine having to create sub-classes for each combination of capability types, e.g., `HobbitWithRing`, `HobbitWithSword`, `HobbitWithRingAndSword`, and so on. This isn't very practical and certainly isn't manageable when we factor in an increasing number of different abilities.

The Decorator pattern isn't heavily tied to how objects are created but instead focuses on the problem of extending their functionality. Rather than just relying on prototypal inheritance, we work with a single base class and progressively add decorator objects which provide additional capabilities. The idea is that rather than sub-classing, we add (decorate) properties or methods to a base object, so it's a little more streamlined.

We can use JavaScript classes to create the base classes that can be decorated. Adding new attributes or methods to object instances of the class in JavaScript is a very straightforward process. With this in mind, we can implement a very simplistic decorator as follows(Examples 7-5 and 7-6):

Example 7-5. Decorating Constructors with New Functionality

```
// A vehicle constructor
class Vehicle {
  constructor(vehicleType) {
    // some sane defaults
    this.vehicleType = vehicleType || 'car';
    this.model = 'default';
    this.license = '00000-000';
  }
}

// Test instance for a basic vehicle
const testInstance = new Vehicle('car');
console.log(testInstance);

// Outputs:
// vehicle: car, model:default, license: 00000-000

// Lets create a new instance of vehicle, to be decorated
const truck = new Vehicle('truck');

// New functionality we're decorating vehicle with
truck.setModel = function(modelName) {
  this.model = modelName;
};

truck.setColor = function(color) {
  this.color = color;
};

// Test the value setters and value assignment works
correctly
truck.setModel('CAT');
truck.setColor('blue');

console.log(truck);
```

```
// Outputs:
// vehicle:truck, model:CAT, color: blue

// Demonstrate "vehicle" is still unaltered
const secondInstance = new Vehicle('car');
console.log(secondInstance);

// Outputs:
// vehicle: car, model:default, license: 00000-000
```

Here, `truck` is an instance of the class `Vehicle`, and we also decorate it with additional methods `setColor` and `setModel`.

This type of simplistic implementation is functional, but it doesn't demonstrate all the strengths that Decorators offer. For this, we're going to go through my variation of the Coffee example from an excellent book called *Head First Design Patterns* by Freeman, Sierra, and Bates, which is modeled around a Macbook purchase.

Example 7-6. Decorating Objects with Multiple Decorators

```
// The constructor to decorate
class MacBook {
  constructor() {
    this.cost = 997;
    this.screenSize = 11.6;
  }
  getCost() {
    return this.cost;
  }
  getScreenSize() {
    return this.screenSize;
  }
}

// Decorator 1
class Memory extends MacBook {
  constructor(macBook) {
    super();
    this.macBook = macBook;
  }

  getCost() {
```

```

        return this.macBook.getCost() + 75;
    }
}

// Decorator 2
class Engraving extends MacBook {
    constructor(macBook) {
        super();
        this.macBook = macBook;
    }

    getCost() {
        return this.macBook.getCost() + 200;
    }
}

// Decorator 3
class Insurance extends MacBook {
    constructor(macBook) {
        super();
        this.macBook = macBook;
    }

    getCost() {
        return this.macBook.getCost() + 250;
    }
}

// init main object
let mb = new MacBook();

// init decorators
mb = new Memory(mb);
mb = new Engraving(mb);
mb = new Insurance(mb);

// Outputs: 1522
console.log(mb.getCost());

// Outputs: 11.6
console.log(mb.getScreenSize());

```

In the above example, our Decorators are overriding the MacBook

superclass objects `.cost()` function to return the current price of the Macbook plus the cost of the upgrade.

It's considered decoration as the original Macbook objects constructor methods which are not overridden (e.g., `screenSize()`), as well as any other properties which we may define as a part of the Macbook, remain unchanged and intact.

There isn't a defined interface in the above example. We're shifting away from the responsibility of ensuring an object meets an interface when moving from the creator to the receiver.

Pseudoclassical Decorators

We're now going to examine a variation of the Decorator first presented in a JavaScript form in *Pro JavaScript Design Patterns* (PJDP) by Dustin Diaz and Ross Harmes.

Unlike some of the examples from earlier, Diaz and Harmes stick more closely to how decorators are implemented in other programming languages (such as Java or C++) using the concept of an "interface," which we will define in more detail shortly.

NOTE

This particular variation of the Decorator pattern is provided for reference purposes. If you find it overly complex, I recommend opting for one of the straightforward implementations covered earlier.

Interfaces

PJDP describes the Decorator pattern as one that is used to transparently wrap objects inside other objects of the same interface. An interface is a way of defining the methods an object *should* have. However, it doesn't directly specify how you should implement those methods. Interfaces can also

optionally indicate what parameters the methods take.

So, why would we use an interface in JavaScript? The idea is that they're self-documenting and promote reusability. In theory, interfaces make code more stable by ensuring any change to the interface must also be propagated to the objects implementing them.

Below is an example of an implementation of interfaces in JavaScript using duck-typing, . This approach helps determine whether an object is an instance of a constructor/object based on the methods it implements.

```
// Create interfaces using a pre-defined Interface  
// constructor that accepts an interface name and  
// skeleton methods to expose.  
  
// In our reminder example summary() and placeOrder()  
// represent functionality the interface should  
// support  
const reminder = new Interface('List', ['summary',  
  'placeOrder']);  
  
const properties = {  
  name: 'Remember to buy the milk',  
  date: '05/06/2016',  
  actions: {  
    summary() {  
      return 'Remember to buy the milk, we are almost  
out!';  
    },  
    placeOrder() {  
      return 'Ordering milk from your local grocery  
store';  
    },  
  },  
};  
  
// Now create a constructor implementing the above  
properties  
// and methods  
  
class Todo {
```

```

    constructor({ actions, name }) {
        // State the methods we expect to be supported
        // as well as the Interface instance being checked
        // against

        Interface.ensureImplements(actions, reminder);

        this.name = name;
        this.methods = actions;
    }
}

// Create a new instance of our Todo constructor

const todoItem = new Todo(properties);

// Finally test to make sure these function correctly

console.log(todoItem.methods.summary());
console.log(todoItem.methods.placeOrder());

// Outputs:
// Remember to buy the milk, we are almost out!
// Ordering milk from your local grocery store

```

Both classic JavaScript, as well as ES2015+, do not support interfaces. However, we can create our Interface class. In the above, `Interface.ensureImplements` provides strict functionality checking, and you can find code for both this and the `Interface` constructor [here](#).

The biggest problem with interfaces is that since there isn't built-in support for them in JavaScript, there is a risk that we will attempt to emulate a feature of another language that may not be an ideal fit. You can use lightweight interfaces without a significant performance cost, however, and we will next look at *Abstract Decorators* using this same concept.

Abstract Decorators

To demonstrate the structure of this version of the Decorator pattern, we're going to imagine we have a superclass that models a `Macbook` once again

and a store that allows us to “decorate” our Macbook with a number of enhancements for an additional fee.

Enhancements can include upgrades to 4 GB or 8 GB of RAM, engraving, Parallels, or a case. Now, if we were to model this using an individual subclass for each combination of enhancement options, it might look something like this:

```
const Macbook = class {  
  //...  
};  
  
const MacbookWith4GBRam = class {};  
const MacbookWith8GBRam = class {};  
const MacbookWith4GBRamAndEngraving = class {};  
const MacbookWith8GBRamAndEngraving = class {};  
const MacbookWith8GBRamAndParallels = class {};  
const MacbookWith4GBRamAndParallels = class {};  
const MacbookWith8GBRamAndParallelsAndCase = class {};  
const MacbookWith4GBRamAndParallelsAndCase = class {};  
const MacbookWith8GBRamAndParallelsAndCaseAndInsurance =  
class {};  
const MacbookWith4GBRamAndParallelsAndCaseAndInsurance =  
class {};
```

... and so on.

The above solution would be impractical as a new subclass would be required for every possible combination of enhancements that are available. As we would prefer to keep things simple without maintaining a large set of subclasses, let’s look at how we can use decorators to solve this problem better.

Rather than requiring all of the combinations we saw earlier, we will only create five new decorator classes. Methods called on these enhancement classes would be passed on to our Macbook class.

In the following example, decorators transparently wrap around their components and can be interchanged as they use the same interface. Here’s the interface we’re going to define for the Macbook:

```

const Macbook = new Interface('Macbook', [
  'addEngraving',
  'addParallels',
  'add4GBRam',
  'add8GBRam',
  'addCase',
]);

// A Macbook Pro might thus be represented as follows:
class MacbookPro {
  // implements Macbook
}

// ES2015+: We still could use Object.prototype for adding
// new methods,
// because internally we use the same structure

MacbookPro.prototype = {
  addEngraving() {},
  addParallels() {},
  add4GBRam() {},
  add8GBRam() {},
  addCase() {},
  getPrice() {
    // Base price
    return 900.0;
  },
};

```

To make it easier for us to add many more options as needed later on, an Abstract Decorator class is defined with default methods required to implement the **Macbook** interface, which the rest of the options will subclass. Abstract Decorators ensure that we can decorate a base class independently with as many decorators as needed in different combinations (remember the example earlier?) without needing to derive a class for every possible combination.

```

// Macbook decorator abstract decorator class

class MacbookDecorator {

```

```

    constructor(macbook) {
        Interface.ensureImplements(macbook, Macbook);
        this.macbook = macbook;
    }

    addEngraving() {
        return this.macbook.addEngraving();
    }

    addParallels() {
        return this.macbook.addParallels();
    }

    add4GBRam() {
        return this.macbook.add4GBRam();
    }

    add8GBRam() {
        return this.macbook.add8GBRam();
    }

    addCase() {
        return this.macbook.addCase();
    }

    getPrice() {
        return this.macbook.getPrice();
    }
}

```

In the above sample, the **Macbook** Decorator accepts an object (a **Macbook**) to use as our base component. It uses the **Macbook** interface we defined earlier, and each method is just calling the same method on the component. We can now create our option classes for what can be added by using the **Macbook** Decorator.

```

// Let's now extend (decorate) the CaseDecorator
// with a MacbookDecorator

```

```

class CaseDecorator extends MacbookDecorator {
    constructor(macbook) {

```

```

        super(macbook);
    }

    addCase() {
        return `${this.macbook.addCase()}Adding case to
macbook`;
    }

    getPrice() {
        return this.macbook.getPrice() + 45.0;
    }
}

```

We are overriding the `addCase()` and `getPrice()` methods that we want to decorate, and we're achieving this by first calling these methods on the original `MacBook` and then simply appending a string or numeric value (e.g., 45.00) to them accordingly.

As there's been quite a lot of information presented in this section so far; let's try to bring it all together in a single example that will hopefully highlight what we have learned.

```

// Instantiation of the macbook
const myMacbookPro = new MacbookPro();

// Outputs: 900.00
console.log(myMacbookPro.getPrice());

// Decorate the macbook
const decoratedMacbookPro = new
CaseDecorator(myMacbookPro);

// This will return 945.00
console.log(decoratedMacbookPro.getPrice());

```

As decorators can modify objects dynamically, they're a perfect pattern for changing existing systems. Occasionally, it's just simpler to create decorators around an object versus the trouble of maintaining individual subclasses for each object type. This makes maintaining applications that may require many

subclassing objects significantly more straightforward.

You can find a functional version of this example on [JSBin](#).

Advantages and Disadvantages

Developers enjoy using this pattern as it can be used transparently and is somewhat flexible. As we've seen, objects can be wrapped or “decorated” with new behavior and continue to be used without worrying about the base object being modified. In a broader context, this pattern also avoids us needing to rely on large numbers of subclasses to get the same benefits.

There are, however, drawbacks that we should be aware of when implementing the pattern. It can significantly complicate our application architecture if poorly managed, as it introduces many small but similar objects into our namespace. The concern is that other developers unfamiliar with the pattern may have difficulty grasping why it's being used, making it hard to manage.

Sufficient commenting or pattern research should assist with the latter. However, as long as we handle how widely we use the Decorator in our applications, we should be fine on both counts.

Flyweight

The Flyweight pattern is a classical structural solution for optimizing code that is repetitive, slow, and inefficiently shares data. It aims to minimize the use of memory in an application by sharing as much data as possible with related objects (e.g., application configuration, state, and so on—see [Figure 7-8](#)).

Flyweight Pattern

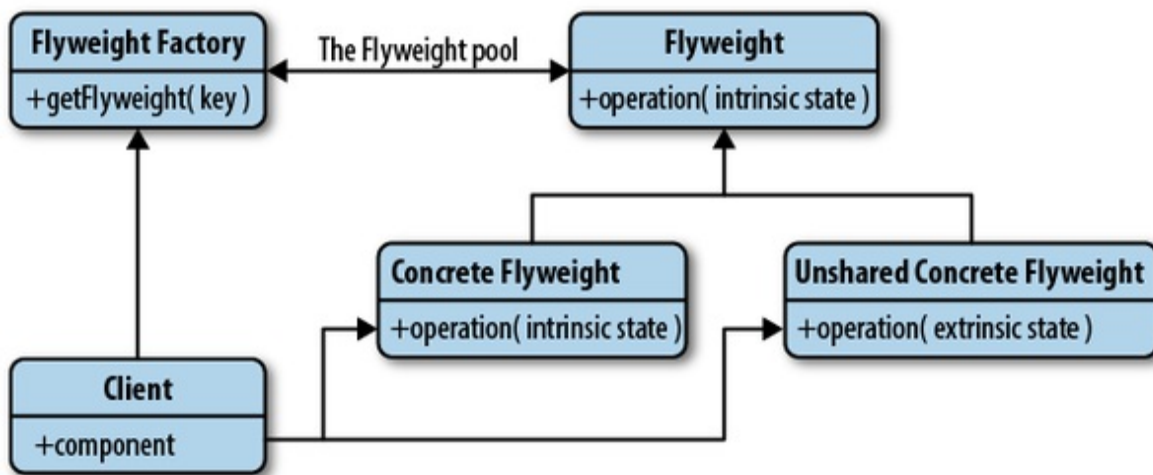

Figure 7-8. Flyweight pattern

Paul Calder and Mark Linton first conceived the pattern in 1990 and named it after the boxing weight class that includes fighters weighing less than 112lb. The name Flyweight is derived from this weight classification as it refers to the small weight (memory footprint) the pattern aims to help us achieve.

In practice, Flyweight data sharing can involve taking several similar objects or data constructs used by many objects and placing this data into a single external object. We can pass this object to those depending on this data rather than storing identical data across each one.

Using Flyweights

There are two ways in which you can apply the Flyweight pattern. The first is at the data layer, where we deal with the concept of sharing data between large quantities of similar objects stored in memory.

You can also apply the Flyweight at the DOM layer as a central event manager to avoid attaching event handlers to every child element in a parent container with similar behavior.

Traditionally the flyweight pattern has been used most at the data layer, so we'll take a look at this first.

Flyweights and Sharing Data

For this application, we need to be aware of a few more concepts around the classical Flyweight pattern. In the Flyweight pattern, there's a concept of two states—intrinsic and extrinsic. Intrinsic information may be required by internal methods in our objects, without which they absolutely cannot function. Extrinsic information can, however, be removed and stored externally.

You can replace objects with the same intrinsic data with a single shared object created by a factory method. This allows us to reduce the overall quantity of implicit data being stored quite significantly.

The benefit is that we can keep an eye on objects that have already been instantiated so that new copies are only ever created should the intrinsic state differ from the object we already have.

We use a manager to handle the extrinsic states. You can implement this in various ways, but one approach is to have the manager object contain a central database of the extrinsic states and the flyweight objects to which they belong.

Implementing Classical Flyweights

As the Flyweight pattern hasn't been heavily used in JavaScript recently, many of the implementations we might use for inspiration come from the Java and C++ worlds.

Our first look at Flyweights in code is my JavaScript implementation of the Java sample of the Flyweight pattern from [Wikipedia](#).

We will be making use of three types of Flyweight components in this implementation, which are listed below:

Flyweight

Corresponds to an interface through which flyweights are able to receive and act on extrinsic states.

Concrete flyweight

Actually implements the Flyweight interface and stores the intrinsic states. Concrete Flyweights need to be sharable and capable of manipulating the extrinsic state.

Flyweight factory

Manages flyweight objects and creates them too. It ensures that our flyweights are shared and manages them as a group of objects that can be queried if we require individual instances. If an object has already been created in the group, it returns it. Otherwise, it adds a new object to the pool and returns it.

These correspond to the following definitions in our implementation:

- `CoffeeOrder`: Flyweight
- `CoffeeFlavor`: Concrete flyweight
- `CoffeeOrderContext`: Helper
- `CoffeeFlavorFactory`: Flyweight factory
- `testFlyweight`: Utilization of our flyweights

Duck punching “implements”

Duck punching allows us to extend the capabilities of a language or solution without necessarily needing to modify the runtime source. As this next solution requires a Java keyword (`implements`) for implementing interfaces and isn't found in JavaScript natively, let's first duck-punch it.

`Function.prototype.implementsFor` works on an object constructor and will accept a parent class (function) or object and either inherit from this using normal inheritance (for functions) or virtual inheritance (for objects).

```
// Simulate pure virtual inheritance/"implement" keyword
```

```

for JS
Function.prototype.implementsFor =
function(parentClassOrObject) {
    if (parentClassOrObject.constructor === Function) {
        // Normal Inheritance
        this.prototype = new parentClassOrObject();
        this.prototype.constructor = this;
        this.prototype.parent =
parentClassOrObject.prototype;
    } else {
        // Pure Virtual Inheritance
        this.prototype = parentClassOrObject;
        this.prototype.constructor = this;
        this.prototype.parent = parentClassOrObject;
    }
    return this;
};

```

We can use this to patch the lack of an `implements` keyword by explicitly having a function inherit an interface. Below, `CoffeeFlavor` implements the `CoffeeOrder` interface and must contain its interface methods for us to assign the functionality powering these implementations to an object.

```

// Flyweight object
const CoffeeOrder = {
    // Interfaces
    serveCoffee(context) {},
    getFlavor() {},
};

// ConcreteFlyweight object that creates ConcreteFlyweight
// Implements CoffeeOrder
function CoffeeFlavor(newFlavor) {
    const flavor = newFlavor;

    // If an interface has been defined for a feature
    // implement the feature
    if (typeof this.getFlavor === 'function') {
        this.getFlavor = () => flavor;
    }
}

```

```

    if (typeof this.serveCoffee === 'function') {
      this.serveCoffee = context => {
        console.log(
          `Serving Coffee flavor ${flavor} to table
${context.getTable()}`
        );
      };
    }
  }
}

```

```

// Implement interface for CoffeeOrder
CoffeeFlavor.implementsFor(CoffeeOrder);

```

```

// Handle table numbers for a coffee order
const CoffeeOrderContext = tableNumber => ({
  getTable() {
    return tableNumber;
  }
});

```

```

const CoffeeFlavorFactory = () => {
  const flavors = {};
  let length = 0;

  return {
    getCoffeeFlavor(flavorName) {
      let flavor = flavors[flavorName];
      if (typeof flavor === 'undefined') {
        flavor = new CoffeeFlavor(flavorName);
        flavors[flavorName] = flavor;
        length++;
      }
      return flavor;
    },

    getTotalCoffeeFlavorsMade() {
      return length;
    },
  };
};

```

```

// Sample usage:
// testFlyweight()

```

```

const testFlyweight = () => {
  // The flavors ordered.
  const flavors = [];

  // The tables for the orders.
  const tables = [];

  // Number of orders made
  let ordersMade = 0;

  // The CoffeeFlavorFactory instance
  const flavorFactory = new CoffeeFlavorFactory();

  function takeOrders(flavorIn, table) {
    flavors.push(flavorFactory.getCoffeeFlavor(flavorIn));
    tables.push(new CoffeeOrderContext(table));
    ordersMade++;
  }

  takeOrders('Cappuccino', 2);
  takeOrders('Cappuccino', 2);
  takeOrders('Frappe', 1);
  takeOrders('Frappe', 1);
  takeOrders('Xpresso', 1);
  takeOrders('Frappe', 897);
  takeOrders('Cappuccino', 97);
  takeOrders('Cappuccino', 97);
  takeOrders('Frappe', 3);
  takeOrders('Xpresso', 3);
  takeOrders('Cappuccino', 3);
  takeOrders('Xpresso', 96);
  takeOrders('Frappe', 552);
  takeOrders('Cappuccino', 121);
  takeOrders('Xpresso', 121);

  for (let i = 0; i < ordersMade; ++i) {
    flavors[i].serveCoffee(tables[i]);
  }
  console.log(' ');
  console.log(
    `total CoffeeFlavor objects made: ` +

```

```
`${flavorFactory.getTotalCoffeeFlavorsMade()}`  
    );  
};
```

Converting Code to Use the Flyweight Pattern

Next, let's continue our look at Flyweights by implementing a system to manage all books in a library. You could list the essential meta-data for each book could probably as follows:

- ID
- Title
- Author
- Genre
- Page count
- Publisher ID
- ISBN

We'll also require the following properties to track which member has checked out a particular book, the date they've checked it out, and the expected return date.

- checkoutDate
- checkoutMember
- dueReturnDate
- availability

We create a **Book** class to represent each book as follows before any optimization using the Flyweight pattern. The constructor takes in all the properties related directly to the book and those required for tracking it.

```
class Book {
    constructor(
        id,
        title,
        author,
        genre,
        pageCount,
        publisherID,
        ISBN,
        checkoutDate,
        checkoutMember,
        dueReturnDate,
        availability
    ) {
        this.id = id;
        this.title = title;
        this.author = author;
        this.genre = genre;
        this.pageCount = pageCount;
        this.publisherID = publisherID;
        this.ISBN = ISBN;
        this.checkoutDate = checkoutDate;
        this.checkoutMember = checkoutMember;
        this.dueReturnDate = dueReturnDate;
        this.availability = availability;
    }

    getTitle() {
        return this.title;
    }

    getAuthor() {
        return this.author;
    }

    getISBN() {
        return this.ISBN;
    }

    // For brevity, other getters are not shown
    updateCheckoutStatus(
        bookID,
        newStatus,
```

```

        checkoutDate,
        checkoutMember,
        newReturnDate
    ) {
        this.id = bookID;
        this.availability = newStatus;
        this.checkoutDate = checkoutDate;
        this.checkoutMember = checkoutMember;
        this.dueReturnDate = newReturnDate;
    }

    extendCheckoutPeriod(bookID, newReturnDate) {
        this.id = bookID;
        this.dueReturnDate = newReturnDate;
    }

    isPastDue(bookID) {
        const currentDate = new Date();
        return currentDate.getTime() >
Date.parse(this.dueReturnDate);
    }
}

```

This probably works fine initially for small collections of books. However, as the library expands to include a more extensive inventory with multiple versions and copies of each book, we may find the management system running slower and slower over time. Using thousands of book objects may overwhelm the available memory, but we can optimize our system using the Flyweight pattern to improve this.

We can now separate our data into intrinsic and extrinsic states : data relevant to the book object (title, author, etc.) is intrinsic, while the checkout data (checkoutMember, dueReturnDate, etc.) is considered extrinsic. Effectively, this means that only one **BOOK** object is required for each combination of book properties. It's still a considerable number of objects, but significantly fewer than we had previously.

An instance of the following book meta-data combination will be created for all required copies of the book object with a particular title/ISBN.

```
// Flyweight optimized version
class Book {
  constructor(title, author, genre, pageCount, publisherID,
ISBN) {
    this.title = title;
    this.author = author;
    this.genre = genre;
    this.pageCount = pageCount;
    this.publisherID = publisherID;
    this.ISBN = ISBN;
  }
}
```

As we can see, the extrinsic states have been removed. Everything to do with library check-outs will be moved to a manager, and as the object data is now segmented, we can use a factory for instantiation.

A Basic Factory

Let's now define a very basic factory. We will have it check if a book with a particular title has been previously created inside the system; if it has, we'll return it—if not, a new book will be created and stored so that it can be accessed later. This makes sure that we only create a single copy of each unique intrinsic piece of data:

```
// Book Factory singleton
const existingBooks = {};

class BookFactory {
  constructor(title, author, genre, pageCount,
publisherID, ISBN) {

    // Find if a particular book + metadata combination
    already exists
    // !! or (bang bang) forces a boolean to be
    returned
    this.existingBook = existingBooks[ISBN];
    if (!!this.existingBook) {
      return this.existingBook;
    } else {
```

```

        // if not, let's create a new instance of the
        book and store it
        const book = new Book(title, author,
                                genre, pageCount, publisherID,
ISBN);
        existingBooks[ISBN] = book;
        return book;
    }
}

```

Managing the Extrinsic States

Next, we need to store the states that were removed from the **BOOK** objects somewhere—luckily, a manager (which we’ll be defining as a Singleton) can be used to encapsulate them. Combinations of a **BOOK** object and the library member who’s checked it out will be called Book record. Our manager will be storing both and will include checkout-related logic we stripped out during our flyweight optimization of the **Book** class.

```

// BookRecordManager singleton
const bookRecordDatabase = {};

class BookRecordManager {
    // add a new book into the library system
    constructor(id, title, author, genre, pageCount,
publisherID, ISBN,
                checkoutDate, checkoutMember, dueReturnDate,
availability) {
        this.book = new BookFactory(title, author, genre,
pageCount,
                                publisherID, ISBN);

        bookRecordDatabase[id] = {
            checkoutMember,
            checkoutDate,
            dueReturnDate,
            availability,

```

```

        book: this.book,
    };
}

updateCheckoutStatus(bookID, newStatus, checkoutDate,
                    checkoutMember, newReturnDate)
{
    const record = bookRecordDatabase[bookID];
    record.availability = newStatus;
    record.checkoutDate = checkoutDate;
    record.checkoutMember = checkoutMember;
    record.dueReturnDate = newReturnDate;
}

extendCheckoutPeriod(bookID, newReturnDate) {
    bookRecordDatabase[bookID].dueReturnDate =
newReturnDate;
}

isPastDue(bookID) {
    const currentDate = new Date();
    return currentDate.getTime() >

Date.parse(bookRecordDatabase[bookID].dueReturnDate);
}
}

```

The result of these changes is that all of the data extracted from the `Book` class is now being stored in an attribute of the `BookManager` singleton (`BookDatabase`)—something considerably more efficient than the large number of objects we were previously using. Methods related to book checkouts are also now based here as they deal with extrinsic rather than intrinsic data.

This process does add a little complexity to our final solution. However, it's a minor concern compared to the performance issues that we have tackled. Data-wise, if we have 30 copies of the same book, we are now only storing it once. Also, every function takes up memory. With the flyweight pattern, these functions exist in one place (on the manager) and not on every object,

thus saving on memory use. For the unoptimized version flyweight mentioned above, we store just a link to the function object as we used the Book constructor's prototype. Still, if we implemented it another way, functions would be created for every book instance.

The Flyweight Pattern and the DOM

The DOM (Document Object Model) supports two approaches that allow objects to detect events—either top-down (event capture) or bottom-up (event bubbling).

In event capture, the event is first captured by the outer-most element and propagated to the inner-most element. In event bubbling, the event is captured and given to the inner-most element and then propagated to the outer elements.

Gary Chisholm wrote one of the best metaphors for describing Flyweights in this context, and it goes a little like this:

Try to think of the flyweight in terms of a pond. A fish opens its mouth (the event), bubbles rise to the surface (the bubbling), a fly sitting on the top flies away when the bubble reaches the surface (the action). In this example we can easily transpose the fish opening its mouth to a button being clicked, the bubbles as the bubbling effect, and the fly flying away to some function being run.

Bubbling was introduced to handle situations in which a single event (e.g., a click) may be handled by multiple event handlers defined at different levels of the DOM hierarchy. Where this happens, event bubbling executes event handlers defined for specific elements at the lowest level possible. From there on, the event bubbles up to containing elements before going to those even higher up.

Flyweights can be used to further tweak the event bubbling process, as we will see shortly ([Example 7-7](#)).

Example: Centralized event handling

For our first practical example, imagine we have several similar elements in a document with similar behavior executed when a user action (e.g., click, mouse-over) is performed against them.

Usually, when constructing our accordion component, menu, or other list-based widgets, we bind a click event to each link element in the parent container (e.g., `$('ul li a').on(. .)`). Instead of binding the click to multiple elements, we can easily attach a Flyweight to the top of our container, which can listen for events coming from below. These can then be handled using logic as simple or complex as required.

As the types of components mentioned often have the same repeating markup for each section (e.g., each section of an accordion), there's a good chance the behavior of each element clicked will be pretty similar and relative to similar classes nearby. We'll use this information to construct a very basic accordion using the Flyweight below.

A `stateManager` namespace is used here to encapsulate our flyweight logic, while jQuery is used to bind the initial click to a container `div`. An `unbind` event is first applied to ensure that no other logic on the page attaches similar handles to the container.

To establish exactly what child element in the container is clicked, we use a `target` check which provides a reference to the element that was clicked, regardless of its parent. We then use this information to handle the click event without actually needing to bind the event to specific children when our page loads.

Example 7-7. Centralized event handling

```
<div id="container">
  <div class="toggle" href="#">More Info (Address)
    <span class="info">
      This is more information
    </span></div>
  <div class="toggle" href="#">Even More Info (Map)
    <span class="info">
      <iframe src="MAPS_URL"></iframe>
    </span>
  </div>
```

```

</div>
const stateManager = {
  fly() {
    const self = this;

    $('#container')
      .unbind()
      .on('click', 'div.toggle', ({
        target
      }) => {
        self.handleClick(target);
      });
  },

  handleClick(elem) {
    $(elem)
      .find('span')
      .toggle('slow');
  },
};

```

The benefit here is that we're converting many independent actions into shared ones (potentially saving on memory).

Behavioral Patterns

Behavioral patterns help define the communication between objects. They help to improve or streamline the communication between disparate objects in a system.

Following are the JavaScript behavioral patterns that we will discuss in this section.

- “The Observer Pattern”
- “The Mediator Pattern”
- “The Command Pattern”

The Observer Pattern

The Observer pattern allows you to notify one object when another object changes without requiring the object to know about its dependents. Often this is a pattern where an object (known as a subject) maintains a list of objects depending on it (observers), automatically notifying them of any changes to its state. In modern frameworks, the observer pattern is used to inform components of state changes. The figure **Figure 7-9** illustrates this.

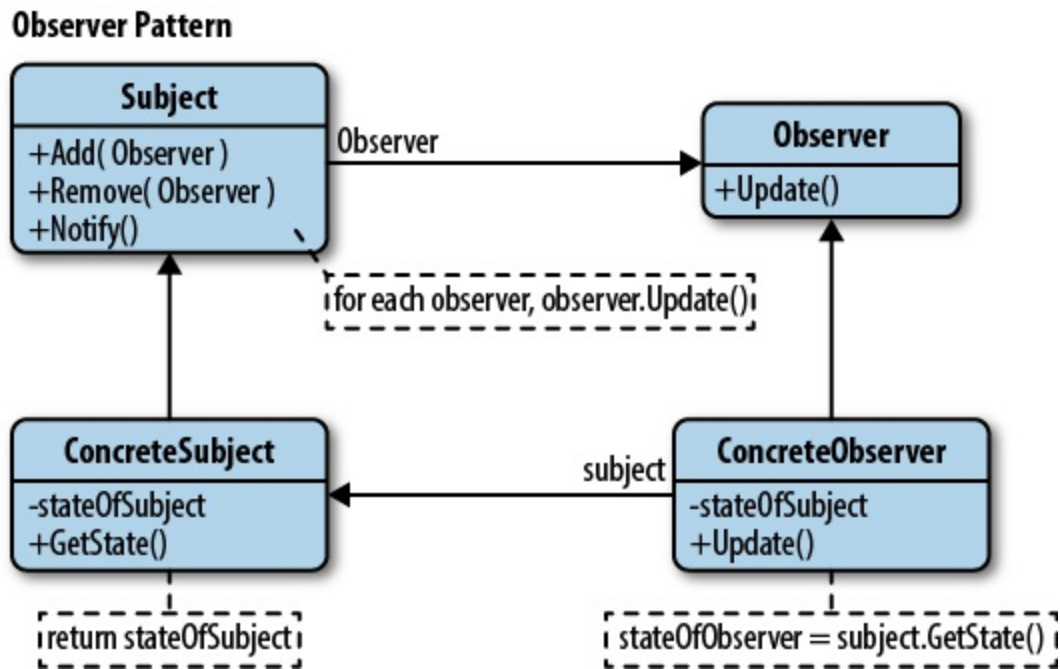

Figure 7-9. Observer pattern

When a subject needs to notify observers about something interesting happening, it broadcasts a notification to the observers (which can include specific data related to the topic). When an observer no longer wishes to be notified of changes by the subject, they can be removed from the list of observers.

It's helpful to refer back to published definitions of design patterns that are language agnostic to get a broader sense of their usage and advantages over time. The definition of the Observer pattern provided in the GoF book, *Design Patterns: Elements of Reusable Object-Oriented Software*, is:[quote]

One or more observers are interested in the state of a subject and register

their interest with the subject by attaching themselves. When something changes in our subject that the observer may be interested in, a notify message is sent which calls the update method in each observer. When the observer is no longer interested in the subject's state, they can simply detach themselves.

We can now expand on what we've learned to implement the Observer pattern with the following components:

Subject

Maintains a list of observers, facilitates adding or removing observers

Observer

Provides an `update` interface for objects that need to be notified of a Subject's changes in state

`ConcreteSubject`

Broadcasts notifications to Observers on changes of state, stores the state of `ConcreteObservers`

`ConcreteObserver`

Stores a reference to the `ConcreteSubject`, implements an `update` interface for the Observer to ensure the state is consistent with the Subject's

ES2015+ allows us to implement the observer pattern using JavaScript classes for observers and subjects with methods for `notify` and `update`.

First, let's model the list of dependent Observers a subject may have using the `ObserverList` class:

```
class ObserverList {  
  constructor() {  
    this.observerList = [];  
  }  
}
```

```

    add(obj) {
        return this.observerList.push(obj);
    }

    count() {
        return this.observerList.length;
    }

    get(index) {
        if (index > -1 && index < this.observerList.length)
        {
            return this.observerList[index];
        }
    }

    indexOf(obj, startIndex) {
        let i = startIndex;

        while (i < this.observerList.length) {
            if (this.observerList[i] === obj) {
                return i;
            }
            i++;
        }

        return -1;
    }

    removeAt(index) {
        this.observerList.splice(index, 1);
    }
}

```

Next, let's model the Subject class that can add, remove, or notify observers on the observer list.

```

class Subject {
    constructor() {
        this.observers = new ObserverList();
    }

    addObserver(observer) {

```

```

    this.observers.add(observer);
  }

  removeObserver(observer) {

    this.observers.removeAt(this.observers.indexOf(observer,
0));
  }

  notify(context) {
    const observerCount = this.observers.count();
    for (let i = 0; i < observerCount; i++) {
      this.observers.get(i).update(context);
    }
  }
}

```

We then define a skeleton for creating new Observers. We will overwrite the `Update` functionality here later with custom behavior.

```

// The Observer
class Observer {
  constructor() {}
  update() {
    // ...
  }
}

```

In our sample application using the above Observer components, we now define:

- A button for adding new observable checkboxes to the page.
- A control checkbox will act as a subject, notifying other checkboxes that they should update to the checked state.
- A container for the new checkboxes added.

We then define `ConcreteSubject` and `ConcreteObserver` handlers to add new observers to the page and implement the updating interface. For

this, we use inheritance to extend our Subject and Observer classes. The `ConcreteSubject` class encapsulates a checkbox and generates a notification when the main checkbox is clicked. `ConcreteObserver` encapsulates each of the observing checkboxes and implements the `Update` interface by changing the checked value of the checkboxes. See below for inline comments on how these work together in the context of our example.

Here is the HTML code:

```
<button id="addNewObserver">Add New Observer  
checkbox</button>  
<input id="mainCheckbox" type="checkbox"/>  
<div id="observersContainer"></div>
```

Here is a sample script:

```
// References to our DOM elements  
  
// Concrete Subject  
class ConcreteSubject extends Subject {  
  constructor(element) {  
    // Call the constructor of the super class.  
    super();  
    this.element = element;  
  
    // Clicking the checkbox will trigger notifications  
    to its observers  
    this.element.onclick = () => {  
      this.notify(this.element.checked);  
    };  
  }  
}  
  
// Concrete Observer  
  
class ConcreteObserver extends Observer {  
  constructor(element) {  
    super();  
    this.element = element;  
  }  
}
```

```

    // Override with custom update behaviour
    update(value) {
      this.element.checked = value;
    }
  }

  // References to our DOM elements
  const addBtn = document.getElementById('addNewObserver');
  const container =
document.getElementById('observersContainer');
  const controlCheckbox = new ConcreteSubject(
    document.getElementById('mainCheckbox')
  );

  const addNewObserver = () => {
    // Create a new checkbox to be added
    const check = document.createElement('input');
    check.type = 'checkbox';
    const checkObserver = new ConcreteObserver(check);

    // Add the new observer to our list of observers
    // for our main subject
    controlCheckbox.addObserver(checkObserver);

    // Append the item to the container
    container.appendChild(check);
  };

  addBtn.onclick = addNewObserver;
}

```

In this example, we looked at how to implement and utilize the Observer pattern, covering the concepts of a Subject, Observer, ConcreteSubject, and ConcreteObserver.

Differences Between the Observer and Publish/Subscribe Pattern

While it's helpful to be aware of the Observer pattern quite often in the

JavaScript world, we'll find it commonly implemented using a variation known as the Publish/Subscribe pattern. Although the two patterns are pretty similar, there are differences worth noting.

The Observer pattern requires that the observer (or object) wishing to receive topic notifications must subscribe this interest to the object firing the event (the subject), as seen in **Figure 7-10**.

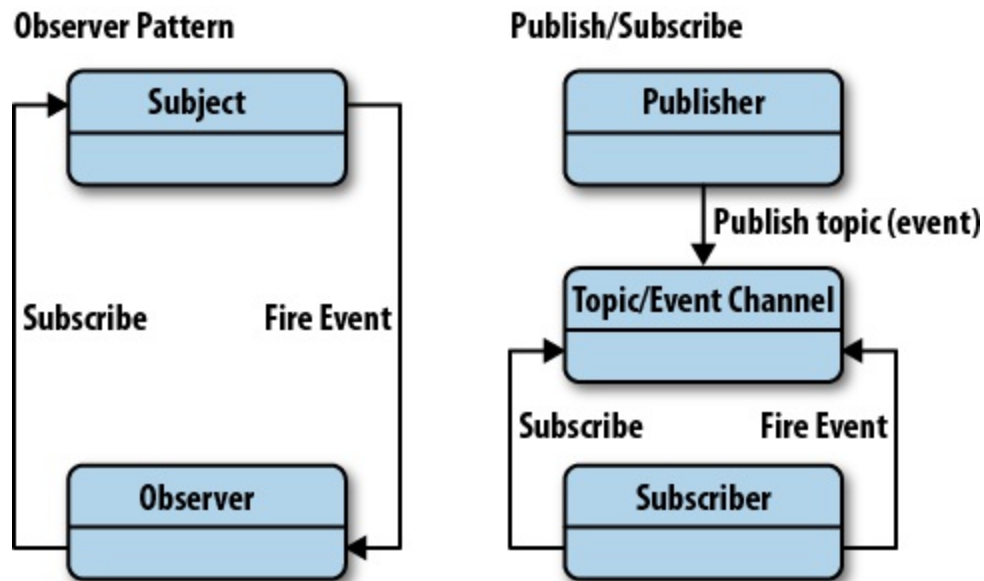

Figure 7-10. Publish/Subscribe

The Publish/Subscribe pattern, however, uses a topic/event channel that sits between the objects wishing to receive notifications (subscribers) and the object firing the event (the publisher). This event system allows code to define application-specific events, which can pass custom arguments containing values needed by the subscriber. The idea here is to avoid dependencies between the subscriber and publisher.

This differs from the Observer pattern as it allows any subscriber implementing an appropriate event handler to register for and receive topic notifications broadcast by the publisher.

Here is an example of how one might use the Publish/Subscribe pattern if provided with a functional implementation powering `publish()`, `subscribe()`, and `unsubscribe()` behind the scenes:

```

// A very simple new mail handler

// A count of the number of messages received
let mailCounter = 0;

// Initialize subscribers that will listen out for a topic
// with the name "inbox/newMessage".

// Render a preview of new messages
const subscriber1 = subscribe('inbox/newMessage', (topic,
data) => {
  // Log the topic for debugging purposes
  console.log('A new message was received: ', topic);

  // Use the data that was passed from our subject
  // to display a message preview to the user
  $('#messageSender').html(data.sender);
  $('#messagePreview').html(data.body);
});

// Here's another subscriber using the same data to perform
// a different task.

// Update the counter displaying the number of new
// messages received via the publisher

const subscriber2 = subscribe('inbox/newMessage', (topic,
data) => {
  $('#newMessageCounter').html(++mailCounter);
});

publish('inbox/newMessage', [
  {
    sender: 'hello@google.com',
    body: 'Hey there! How are you doing today?',
  },
]);

// We could then at a later point unsubscribe our
subscribers
// from receiving any new topic notifications as follows:
// unsubscribe( subscriber1 );
// unsubscribe( subscriber2 );

```

The general idea here is the promotion of loose coupling. Rather than single objects calling on the methods of other objects directly, they instead subscribe to a specific task or activity of another object and are notified when it occurs.

Advantages

The Observer and Publish/Subscribe patterns encourage us to think hard about the relationships between different application parts. They also help us identify layers containing direct relationships that could be replaced with sets of subjects and observers. This effectively could be used to break down an application into smaller, more loosely coupled blocks to improve code management and potential for reuse.

Further motivation for using the Observer pattern is in situations where we need to maintain consistency between related objects without making classes tightly coupled. For example, when an object needs to be able to notify other objects without making assumptions regarding those objects.

Dynamic relationships can exist between observers and subjects when using either pattern. This provides excellent flexibility that may not be as easy to implement when disparate parts of our application are tightly coupled.

While it may not always be the best solution to every problem, these patterns remain one of the best tools for designing decoupled systems and should be considered an essential tool in any JavaScript developer's utility belt.

Disadvantages

Consequently, some of the issues with these patterns actually stem from their main benefits. In Publish/Subscribe, by decoupling publishers from subscribers, it can sometimes become difficult to obtain guarantees that particular parts of our applications are functioning as we may expect.

For example, publishers may assume that one or more subscribers are listening to them. Say that we're using such an assumption to log or output errors regarding some application process. If the subscriber performing the

logging crashes (or for some reason fails to function), the publisher won't have a way of seeing this due to the decoupled nature of the system.

Another drawback of the pattern is that subscribers are entirely ignorant of the existence of each other and are blind to the cost of switching publishers. Due to the dynamic relationship between subscribers and publishers, it can be difficult to track an update dependency.

Publish/Subscribe Implementations

Publish/Subscribe fits in very well in JavaScript ecosystems, primarily because, at the core, ECMAScript implementations are event-driven. This is particularly true in browser environments, as the DOM uses events as its main interaction API for scripting.

That said, neither ECMAScript nor DOM provide core objects or methods for creating custom event systems in implementation code (except for perhaps the DOM3 CustomEvent, which is bound to the DOM and is thus not generically applicable).

Luckily, many modern JavaScript libraries support utilities for implementing a Publish/Subscribe system with little effort. For those wishing to use the Publish/Subscribe pattern with vanilla JavaScript (or another library), **PubSubJS** is a topic-based publish/subscribe library written in JavaScript. **Postal.js** is an in-memory message bus that implements channels and topic-based messaging. **AmplifyJS** includes a clean, library-agnostic implementation that you can use with any library or toolkit.

A Publish/Subscribe implementation

To better appreciate how many of the vanilla JavaScript implementations of the Observer pattern might work, let's take a walkthrough of a minimalist version of Publish/Subscribe I released on GitHub under a project called **pubsubz**. This demonstrates the core concepts of subscribe and publish, and the idea of unsubscribing.

I've opted to base our examples on this code as it sticks closely to the method

signatures and implementation approach I expect to see in a JavaScript version of the classic Observer pattern.

```
class PubSub {
  constructor() {
    // Storage for topics that can be broadcast
    // or listened to
    this.topics = {};

    // A topic identifier
    this.subUid = -1;
  }

  publish(topic, args) {
    if (!this.topics[topic]) {
      return false;
    }

    const subscribers = this.topics[topic];
    let len = subscribers ? subscribers.length : 0;

    while (len--) {
      subscribers[len].func(topic, args);
    }

    return this;
  }

  subscribe(topic, func) {
    if (!this.topics[topic]) {
      this.topics[topic] = [];
    }

    const token = (++this.subUid).toString();
    this.topics[topic].push({
      token,
      func,
    });
    return token;
  }

  unsubscribe(token) {
```

```

        for (const m in this.topics) {
            if (this.topics[m]) {
                for (let i = 0, j = this.topics[m].length;
i < j; i++) {
                    if (this.topics[m][i].token === token)
                    {
                        this.topics[m].splice(i, 1);

                        return token;
                    }
                }
            }
        }
        return this;
    }
}

const pubsub = new PubSub();

pubsub.publish('/addFavorite', ['test']);
pubsub.subscribe('/addFavorite', (topic, args) => {
    console.log('test', topic, args);
});

```

Here we have defined a basic PubSub class that contains

- A list of topics with subscribers who have subscribed to it.
- The Subscribe method creates a new subscriber to a topic using the function to be called when publishing a topic and a unique token.
- The Unsubscribe method removes a subscriber from the list based on the token value passed. The * The Publish method publishes content on a given topic to all its subscribers by calling the registered function.

Using our implementation

We can now use the implementation to publish and subscribe to events of interest as follows (Example 7-8):

Example 7-8. Using our implementation

```

// Another simple message handler

// A simple message logger that logs any topics and data
received through our
// subscriber
const messageLogger = (topics, data) => {
  console.log(`Logging: ${topics}: ${data}`);
};

// Subscribers listen for topics they have subscribed to and
// invoke a callback function (e.g messageLogger) once a new
// notification is broadcast on that topic
const subscription = pubsub.subscribe('inbox/newMessage',
messageLogger);

// Publishers are in charge of publishing topics or
notifications of
// interest to the application. e.g:

pubsub.publish('inbox/newMessage', 'hello world!');

// or
pubsub.publish('inbox/newMessage', ['test', 'a', 'b', 'c']);

// or
pubsub.publish('inbox/newMessage', {
  sender: 'hello@google.com',
  body: 'Hey again!',
});

// We can also unsubscribe if we no longer wish for our
subscribers
// to be notified
pubsub.unsubscribe(subscription);

// Once unsubscribed, this for example won't result in our
// messageLogger being executed as the subscriber is
// no longer listening
pubsub.publish('inbox/newMessage', 'Hello! are you still
there?');

```

User-interface notifications

Next, let's imagine we have a web application responsible for displaying real-time stock information.

The application might have a grid displaying the stock stats and a counter indicating the last update point. The application must update the grid and counter when the data model changes. In this scenario, our subject (which will be publishing topics/notifications) is the data model, and our subscribers are the grid and counter.

When our subscribers are notified that the model has changed, they can update themselves accordingly.

In our implementation, our subscriber will listen to the topic `newDataAvailable` to find out if new stock information is available. If a new notification is published to this topic, it will trigger `gridUpdate` to add a new row to our grid containing this information. It will also update the *last updated* counter to log the last time that data was added (Example 7-9).

Example 7-9. User-interface notifications

```
// Return the current local time to be used in our UI later
getCurrentTime = () => {
  const date = new Date();
  const m = date.getMonth() + 1;
  const d = date.getDate();
  const y = date.getFullYear();
  const t = date.toLocaleTimeString().toLowerCase();

  return `${m}/${d}/${y} ${t}`;
};

// Add a new row of data to our fictional grid component
const addGridRow = data => {
  // ui.grid.addRow( data );
  console.log(`updated grid component with:${data}`);
};

// Update our fictional grid to show the time it was last
// updated
const updateCounter = data => {
  // ui.grid.updateLastChanged( getCurrentTime() );
  console.log(`data last updated at: ${getCurrentTime()}`);
};
```

```

with `${data}`);
};

// Update the grid using the data passed to our subscribers
const gridUpdate = (topic, data) => {
  if (data !== undefined) {
    addGridRow(data);
    updateCounter(data);
  }
};

// Create a subscription to the newDataAvailable topic
const subscriber = pubsub.subscribe('newDataAvailable',
gridUpdate);

// The following represents updates to our data layer. This
could be
// powered by ajax requests which broadcast that new data is
available
// to the rest of the application.

// Publish changes to the gridUpdated topic representing new
entries
pubsub.publish('newDataAvailable', {
  summary: 'Apple made $5 billion',
  identifier: 'APPL',
  stockPrice: 570.91,
});

pubsub.publish('newDataAvailable', {
  summary: 'Microsoft made $20 million',
  identifier: 'MSFT',
  stockPrice: 30.85,
});

```

Decoupling applications using Ben Alman's Pub/Sub implementation

In the following movie rating example, we'll use **Ben Alman's** jQuery implementation of Publish/Subscribe to demonstrate how we can decouple a user interface. Notice how submitting a rating only has the effect of

publishing the fact that new user and rating data is available.

It's left up to the subscribers to those topics to delegate what happens with that data. In our case, we're pushing that new data into existing arrays and then rendering them using the Underscore library's `.template()` method for templating.

Here is the HTML/Templates code (Example 7-10):

Example 7-10. HTML/Templates code for Pub/Sub

```
<script id="userTemplate" type="text/html">
  <li><%= name %></li>
</script>

<script id="ratingsTemplate" type="text/html">
  <li><strong><%= title %></strong> was rated <%= rating
%>/5</li>
</script>

<div id="container">

  <div class="sampleForm">
    <p>
      <label for="twitter_handle">Twitter handle:
</label>
      <input type="text" id="twitter_handle" />
    </p>
    <p>
      <label for="movie_seen">Name a movie you've seen
this year:</label>
      <input type="text" id="movie_seen" />
    </p>
    <p>
      <label for="movie_rating">Rate the movie you saw:
</label>
      <select id="movie_rating">
        <option value="1">1</option>
        <option value="2">2</option>
        <option value="3">3</option>
```

```

        <option value="4">4</option>
        <option value="5" selected>5</option>

    </select>
</p>
<p>

    <button id="add">Submit rating</button>
</p>
</div>

<div class="summaryTable">
    <div id="users"><h3>Recent users</h3></div>
    <div id="ratings"><h3>Recent movies rated</h3></div>
</div>

</div>

```

Here is the JavaScript code (Example 7-11):

Example 7-11. JavaScript code for Pub/Sub

```

;($ => {
    // Pre-compile templates and "cache" them using closure
    const userTemplate =
    _.template($('#userTemplate').html());

    const ratingsTemplate =
    _.template($('#ratingsTemplate').html());

    // Subscribe to the new user topic, which adds a user
    // to a list of users who have submitted reviews
    $.subscribe('/new/user', (e, data) => {
        if (data) {
            $('#users').append(userTemplate(data));
        }
    });

    // Subscribe to the new rating topic. This is composed of
    // a title and
    // rating. New ratings are appended to a running list of
    // added user

```

```

// ratings.
$.subscribe('/new/rating', (e, data) => {
  if (data) {
    $('#ratings').append(ratingsTemplate(data));
  }
});

// Handler for adding a new user
$('#add').on('click', e => {
  e.preventDefault();

  const strUser = $('#twitter_handle').val();
  const strMovie = $('#movie_seen').val();
  const strRating = $('#movie_rating').val();

  // Inform the application a new user is available
  $.publish('/new/user', {
    name: strUser,
  });

  // Inform the app a new rating is available
  $.publish('/new/rating', {
    title: strMovie,
    rating: strRating,
  });
});
})(jQuery);

```

Decoupling an Ajax-based jQuery application

In our final example, we'll take a practical look at how decoupling our code using Pub/Sub early in the development process can save us some potentially painful refactoring later.

Often in Ajax-heavy applications, we want to achieve more than just one unique action once we've received a response to a request. We could add all of the post-request logic into a success callback, but there are drawbacks to this approach.

Highly coupled applications sometimes increase the effort required to reuse functionality due to the increased inter-function/code dependency. Keeping our post-request logic hardcoded in a callback might be okay if we just try to

grab a result set once. However, it's not as appropriate when we want to make further Ajax calls to the same data source (and different end behavior) without rewriting parts of the code multiple times. Rather than going back through each layer that calls the same data source and generalizing them later on, we can use pub/sub from the start and save time.

Using Observers, we can also easily separate application-wide notifications regarding different events down to whatever level of granularity we're comfortable with—something that can be less elegantly done using other patterns.

Notice how in our sample below, one topic notification is made when a user indicates that he wants to make a search query. Another is made when the request returns and actual data is available for consumption. It's left up to the subscribers to then decide how to use knowledge of these events (or the data returned). The benefits of this are that, if we wanted, we could have 10 different subscribers using the data returned in different ways, but as far as the Ajax-layer is concerned, it doesn't care. Its sole duty is to request and return data and then pass it on to whoever wants to use it. This separation of concerns can make the overall design of our code a little cleaner.

Here is the HTML/Templates code ([Example 7-12](#)):

Example 7-12. HTML/Templates code for Ajax

```
<form id="flickrSearch">

    <input type="text" name="tag" id="query"/>

    <input type="submit" name="submit" value="submit"/>

</form>

<div id="lastQuery"></div>

<ol id="searchResults"></ol>
```

```

<script id="resultTemplate" type="text/html">
  <% _.each(items, function( item ){ %>
    <li></li>
  <% });%>
</script>

```

Here is the JavaScript code (Example 7-13):

Example 7-13. JavaScript code for Ajax

```

($ => {
  // Pre-compile template and "cache" it using closure
  const resultTemplate =
_.template($('#resultTemplate').html());

  // Subscribe to the new search tags topic
$.subscribe('/search/tags', (e, tags) => {
  $('#lastQuery').html(`Searched for: ${tags}`);
});

  // Subscribe to the new results topic
$.subscribe('/search/resultSet', (e, results) => {
  $('#searchResults')
    .empty()
    .append(resultTemplate(results));
});

  // Submit a search query and publish tags on the
  /search/tags topic
$('#flickrSearch').submit(function(e) {
  e.preventDefault();
  const tags = $(this)
    .find('#query')
    .val();

  if (!tags) {
    return;
  }

  $.publish('/search/tags', [$.trim(tags)]);
});

  // Subscribe to new tags being published and perform a

```

```

search query
    // using them. Once data has returned publish this data
for the rest
    // of the application to consume We used the
destructuring assignment
    // syntax that makes it possible to unpack values from
data structures
    // into distinct variables.

$.subscribe('/search/tags', (e, tags) => {
    $.getJSON(
'http://api.flickr.com/services/feeds/photos_public.gne?
jsoncallback=?',
    {
        tags,
        tagmode: 'any',
        format: 'json',
    },
    // The destructuring assignment as function parameter
    ({ items }) => {
        if (!items.length) {
            return;
        }
        //shorthand property names in object creation,
        // if variable name equal to object key
        $.publish('/search/resultSet', { items });
    }
    );
});
})(jQuery);

```

Observer Pattern in the React ecosystem

A popular library that uses the observable pattern is RxJS. The RxJS [documentation](#) states that:

ReactiveX combines the Observer pattern with the Iterator pattern and functional programming with collections to fill the need for an ideal way of managing sequences of events.

With RxJS, we can create observers and subscribe to certain events! Let's

look at an example from their documentation, which logs whether a user was dragging in the document.

```
import ReactDOM from "react-dom";
import { fromEvent, merge } from "rxjs";
import { sample, mapTo } from "rxjs/operators";

import "./styles.css";

merge(
  fromEvent(document, "mousedown").pipe(mapTo(false)),
  fromEvent(document, "mousemove").pipe(mapTo(true))
)
.pipe(sample(fromEvent(document, "mouseup")))
.subscribe(isDragging => {
  console.log("Were you dragging?", isDragging);
});

ReactDOM.render(
  <div className="App">Click or drag anywhere and check the
  console!</div>,
  document.getElementById("root")
);
```

The Observer pattern helps decouple several different scenarios in application design. If you haven't been using it, I recommend picking up one of the prewritten implementations mentioned here and giving it a try. It's one of the easier design patterns to get started with but also one of the most powerful.

The Mediator Pattern

The Mediator Pattern is a design pattern that allows one object to notify a set of other objects when an event occurs. The difference between the Mediator and Observer patterns is that the Mediator pattern allows one object to be notified of events that occur in other objects. In contrast, the Observer pattern allows one object to subscribe to multiple events that occur in other objects.

In the section on the Observer pattern, we discussed a way of channeling

multiple event sources through a single object. This is also known as Publish/Subscribe or Event Aggregation. It's common for developers to think of Mediators when faced with this problem, so let's explore how they differ.

The dictionary refers to a mediator as “a neutral party that assists in negotiations and conflict resolution.”² In our world, a mediator is a behavioral design pattern that allows us to expose a unified interface through which the different parts of a system may communicate.

If it appears a system has too many direct relationships between components, it may be time to have a central point of control that components communicate through instead. The Mediator promotes loose coupling by ensuring that interactions between components are managed centrally instead of having components refer to each other explicitly. This can help us decouple systems and improve the potential for component reusability.

A real-world analogy could be a typical airport traffic control system. A tower (mediator) handles what planes can take off and land because all communications (notifications being listened out for or broadcast) take place from the aircraft to the control tower rather than from plane to plane. A centralized controller is a key to the success of this system, and that's the role a Mediator plays in software design(Figure 7-11).

Mediator Pattern

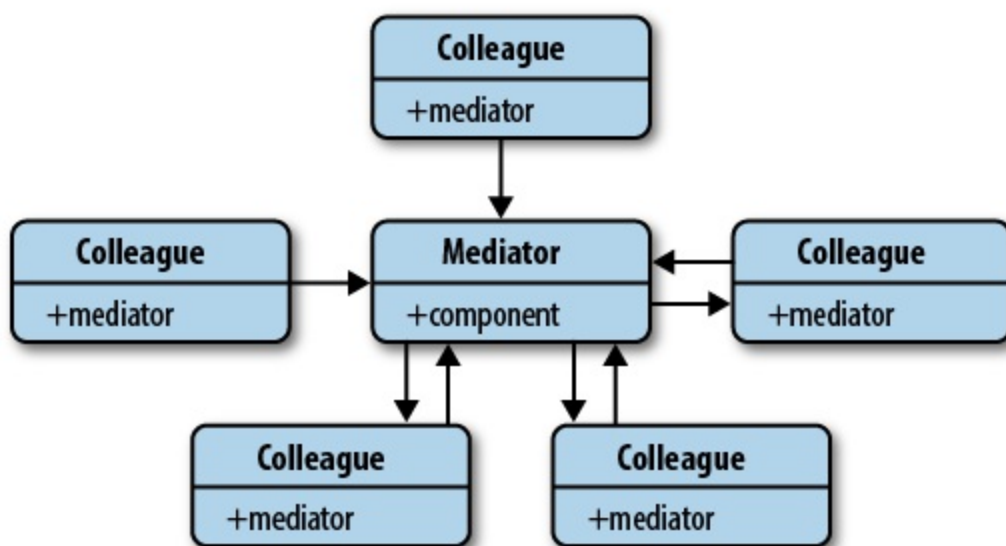

Figure 7-11. Mediator pattern

Another analogy would be DOM event bubbling and event delegation. If all subscriptions in a system are made against the document rather than individual nodes, the document effectively serves as a Mediator. Instead of binding to the events of the individual nodes, a higher-level object is given the responsibility of notifying subscribers about interaction events.

When it comes to the Mediator and Event Aggregator patterns, sometimes it may look like the patterns are interchangeable due to implementation similarities. However, the semantics and intent of these patterns are very different.

And even if the implementations both use some of the same core constructs, I believe there is a distinct difference between them. They should not be interchanged or confused in communication because of their differences.

A Simple Mediator

A Mediator is an object that coordinates interactions (logic and behavior) between multiple objects. It decides when to call which objects based on the actions (or inaction) of other objects and input.

You can write a mediator using a single line of code:

```
const mediator = {};
```

Yes, of course, this is just an object literal in JavaScript. Once again, we're talking about semantics here. The Mediator's purpose is to control the workflow between objects; we really don't need anything more than an object literal to do this.

The following example shows a basic implementation of a mediator object with some utility methods that can trigger and subscribe to events. The `orgChart` object here is a mediator that assigns actions to be taken on the occurrence of a particular event. Here, a manager is assigned to the employee on completing the details of a new employee, and the employee record is saved.

```

const orgChart = {
  addNewEmployee() {
    // getEmployeeDetail provides a view that users
    interact with
    const employeeDetail = this.getEmployeeDetail();

    // when the employee detail is complete, the
    mediator (the 'orgchart'
    // object) decides what should happen next
    employeeDetail.on('complete', employee => {
      // set up additional objects that have
      additional events, which are
      // used by the mediator to do additional things
      const managerSelector =
this.selectManager(employee);
      managerSelector.on('save', employee => {
        employee.save();
      });
    });
  },
  // ...
};

```

I’ve often referred to this type of object as a “workflow” object in the past, but the truth is that it is a mediator. It is an object that handles the workflow between many other objects, aggregating the responsibility of that workflow knowledge into a single object. The result is a workflow that is easier to understand and maintain.

Similarities and Differences

There are, without a doubt, similarities between the event aggregator and mediator examples that I’ve shown here. The similarities boil down to two primary items: events and third-party objects. These differences are superficial at best, though. When we dig into the pattern’s intent and see that the implementations can be dramatically different, the nature of the patterns becomes more apparent.

Events

Both the event aggregator and mediator use events in the above examples. An event aggregator obviously deals with events – it's in the name, after all. The Mediator only uses events because it makes life easy when dealing with modern JavaScript web app frameworks. There is nothing that says a mediator must be built with events. You can build a mediator with callback methods by handing the mediator reference to the child object or using several other means.

The difference, then, is why these two patterns are both using events. The event aggregator, as a pattern, is designed to deal with events. The mediator, though, only uses them because it's convenient.

Third-Party Objects

By design, the event aggregator and mediator use a third-party object to facilitate things. The event aggregator itself is a third party to the event publisher and the event subscriber. It acts as a central hub for events to pass through. The mediator is also a third party to other objects, though. So where is the difference? Why don't we call an event aggregator a mediator? The answer primarily depends on where the application logic and workflow are coded.

In the case of an event aggregator, the third-party object is there only to facilitate the pass-through of events from an unknown number of sources to an unknown number of handlers. All workflow and business logic that needs to be kicked off is put directly into the object that triggers the events and the objects that handle the events.

In the mediator's case, the business logic and workflow are aggregated into the mediator itself. The mediator decides when an object should have its methods called and attributes updated based on factors the mediator knows about. It encapsulates the workflow and process, coordinating multiple objects to produce the desired system behavior. The individual objects involved in this workflow know how to perform their task. But the mediator tells the objects when to perform the tasks by making decisions at a higher

level than the individual objects.

An event aggregator facilitates a “fire and forget” model of communication. The object triggering the event doesn’t care if there are any subscribers. It just fires the event and moves on. A mediator might use events to make decisions, but it is definitely not “fire and forget”. A mediator pays attention to a known set of inputs or activities so that it can facilitate and coordinate other behavior with a known set of actors (objects).

Relationships: When to Use Which

Understanding the similarities and differences between an event aggregator and a mediator is essential for semantic reasons. It’s equally important to know when to use which pattern, though. The basic semantics and intent of the patterns inform the question of when, but experience in using the patterns will help you understand the more subtle points and nuanced decisions that must be made.

Event Aggregator Use

In general, an event aggregator is used when you either have too many objects to listen to directly or have entirely unrelated objects.

When two objects already have a direct relationship – for example, a parent view and a child view – there may be a benefit in using an event aggregator. Have the child view trigger an event, and the parent view can handle the event. This is most commonly seen in Backbone’s Collection and Model in JavaScript framework terms, where all Model events are bubbled up to and through its parent Collection. A Collection often uses model events to modify the state of itself or other models. Handling “selected” items in a collection is an excellent example.

jQuery’s `on` method as an event aggregator is a great example of too many objects to listen to. If you have 10, 20, or 200 DOM elements that can trigger a “click” event, it might be a bad idea to set up a listener on all of them individually. This could quickly deteriorate the performance of the application and user experience. Instead, using jQuery’s `on` method allows us

to aggregate all events and reduce the overhead of 10, 20, or 200 event handlers down to 1.

Indirect relationships are also a great time to use event aggregators. In modern applications, it is ubiquitous to have multiple view objects that need to communicate but have no direct relationship. For example, a menu system might have a view that handles the menu item clicks. But we don't want the menu to be directly tied to the content views showing all the details and information when a menu item is clicked—having the content and menu coupled together would make the code very difficult to maintain in the long run. Instead, we can use an event aggregator to trigger “menu:click:foo” events and have a “foo” object handle the click event to show its content on the screen.

Mediator Use

A mediator is best applied when two or more objects have an indirect working relationship, and business logic or workflow needs to dictate the interactions and coordination of these objects. A wizard interface is an excellent example of this, as shown in the “orgChart” the example above. Multiple views facilitate the entire workflow of the wizard. Rather than tightly coupling the view together by having them reference each other directly, we can decouple them and more explicitly model the workflow between them by introducing a mediator.

The mediator extracts the workflow from the implementation details and creates a more natural abstraction at a higher level, showing us at a much faster glance what that workflow is. We no longer have to dig into the details of each view in the workflow to see what the workflow is.

Event Aggregator (Pub/Sub) and Mediator Together

The crux of the difference between an event aggregator and a mediator, and why these pattern names should not be interchanged, is best illustrated by

showing how they can be used together. The menu example for an event aggregator is the perfect place to introduce a mediator.

Clicking a menu item may trigger a series of changes throughout an application. Some of these changes will be independent of others, and using an event aggregator makes sense. Some of these changes may be internally related, though, and may use a mediator to enact those changes.

A mediator could then be set up to listen to the event aggregator. It could run its logic and process to facilitate and coordinate many objects related to each other but unrelated to the original event source.

```
const MenuItem = MyFrameworkView.extend({
  events: {
    'click .thatThing': 'clickedIt',
  },

  clickedIt(e) {
    e.preventDefault();

    // assume this triggers "menu:click:foo"

    MyFramework.trigger(`menu:click:${this.model.get('name')}`)
  },
});

// ... somewhere else in the app

class MyWorkflow {
  constructor() {
    MyFramework.on('menu:click:foo', this.doStuff,
this);
  }

  static doStuff() {
    // instantiate multiple objects here.
    // set up event handlers for those objects.
    // coordinate all of the objects into a meaningful
workflow.
  }
}
```

```
}
```

In this example, when the MenuItem with the right model is clicked, the `menu:click:foo` event will be triggered. An instance of the `MyWorkflow` class will handle this specific event and coordinate all of the objects it knows about to create the desired user experience and workflow.

We have thus combined an event aggregator and a mediator to create a meaningful experience in both code and application. We now have a clean separation between the menu and the workflow through an event aggregator, and we are still keeping the workflow clean and maintainable through a mediator.

Mediator/Middleware in modern JavaScript

`Express.js` is a popular web application server framework. We can add callbacks to certain routes that the user can access.

Say we want to add a header to the request if the user hits the root (/). We can add this header in a middleware callback.

```
const app = require("express")();

app.use("/", (req, res, next) => {
  req.headers["test-header"] = 1234;
  next();
});
```

The `next()` method calls the next callback in the request-response cycle. We'd create a chain of middleware functions that sit between the request and the response or vice versa. We can track and modify the request object all the way to the response through one or multiple middleware functions.

The middleware callbacks will be invoked whenever the user hits a root endpoint (/).

```
const app = require("express")();
const html = require("./data");
```

```

app.use(
  "/",
  (req, res, next) => {
    req.headers["test-header"] = 1234;
    next();
  },
  (req, res, next) => {
    console.log(`Request has test header:
${!!req.headers["test-header"]}`);
    next();
  }
);

app.get("/", (req, res) => {
  res.set("Content-Type", "text/html");
  res.send(Buffer.from(html));
});

app.listen(8080, function() {
  console.log("Server is running on 8080");
});

```

Mediator Vs. Facade

We will be covering the Facade pattern shortly, but for reference purposes, some developers may also wonder whether there are similarities between the Mediator and Facade patterns. They both abstract the functionality of existing modules, but there are some subtle differences.

The Mediator centralizes communication between modules where these modules explicitly reference it. In a sense, this is multidirectional. The Facade, however, defines a more straightforward interface to a module or system but doesn't add any additional functionality. Other modules in the system aren't directly aware of the concept of a facade and could be considered unidirectional.

The Command Pattern

The Command pattern aims to encapsulate method invocation, requests, or operations into a single object and allows us to both parameterize and pass method calls that can be executed at our discretion. In addition, it enables us to decouple objects invoking the action from the objects that implement them, giving us greater flexibility in swapping out concrete *classes* (objects).

Concrete classes are best explained in terms of class-based programming languages and are related to the idea of abstract classes. An *abstract* class defines an interface, but doesn't necessarily provide implementations for all its member functions. It acts as a base class from which others are derived. A derived class that implements the missing functionality is called a *concrete* class (Figure 7-12). Base and concrete classes can be implemented in JavaScript(ES2015+) using the `extends` keyword applicable to the JavaScript classes.

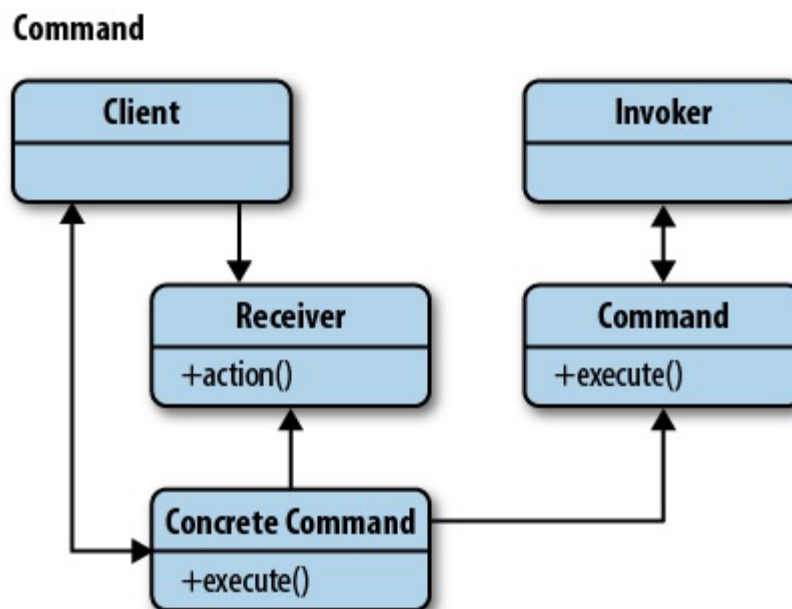

Figure 7-12. Command pattern

The general idea behind the Command pattern is that it provides a means to separate the responsibilities of issuing commands from anything executing commands, delegating this responsibility to different objects instead.

Implementation-wise, simple command objects bind the action and the object wishing to invoke the action. They consistently include an execution

operation (such as `run()` or `execute()`). All Command objects with the same interface can easily be swapped as needed, which is one of the vital benefits of the pattern.

To demonstrate the Command pattern we will create a simple car purchasing service.

```
const CarManager = {
  // request information
  requestInfo(model, id) {
    return `The information for ${model} with ID
    ${id} is foobar`;
  },

  // purchase the car
  buyVehicle(model, id) {
    return `You have successfully purchased Item
    ${id}, a ${model}`;
  },

  // arrange a viewing
  arrangeViewing(model, id) {
    return `You have booked a viewing of ${model} (
    ${id} )`;
  },
};
```

The `CarManager` object is our command object responsible for issuing commands to request information about a car, buy a car, and arrange a viewing. It would be trivial to invoke our `CarManager` methods by directly accessing the object. It would be forgivable to assume nothing is wrong with this—technically, it's completely valid JavaScript. There are, however, scenarios where this may be disadvantageous.

For example, imagine if the core API behind the `CarManager` changed. This would require all objects directly accessing these methods within our application to be modified. It is a type of coupling that effectively goes against the OOP methodology of loosely coupling objects as much as possible. Instead, we could solve this problem by abstracting the API away

further.

Let's now expand the `CarManager` so that our Command pattern application results in the following: accept any named methods that can be performed on the `CarManager` object, passing along any data that might be used, such as the Car model and ID.

Here is what we would like to be able to achieve:

```
CarManager.execute('buyVehicle', 'Ford Escort', '453543');
```

As per this structure, we should now add a definition for the `carManager.execute` method as follows:

```
carManager.execute = function(name) {  
    return (  
        carManager[name] &&  
        carManager[name].apply(carManager,  
        [].slice.call(arguments, 1))  
    );  
};
```

Our final sample calls would thus look as follows:

```
carManager.execute('arrangeViewing', 'Ferrari', '14523');  
carManager.execute('requestInfo', 'Ford Mondeo', '54323');  
carManager.execute('requestInfo', 'Ford Escort', '34232');  
carManager.execute('buyVehicle', 'Ford Escort', '34232');
```

Summary

With that, we can conclude our discussion of traditional design patterns you can use when designing classes, objects, and modules. I have tried incorporating an ideal mix of creational, structural, and behavioral patterns. We have also studied patterns created for classic object-oriented programming languages such as Java and C++ and adapted them for JavaScript.

These patterns will help us design many domain-specific objects (e.g., shopping cart, vehicle, or book) that make up our applications' business model. In the next chapter, we will look at the larger picture of how we can structure applications so that this model delivers to the other application layers, such as the view or the presenter.

Chapter 8. JavaScript MV* Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 8th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

Object design and application architecture are the two principal aspects of application design. We have covered patterns that relate to the first in the previous chapter. In this chapter, we’re going to review three fundamental architectural patterns: MVC (Model-View-Controller), MVP (Model-View-Presenter), and MVVM (Model-View-ViewModel). In the past, these patterns were heavily used for structuring desktop and server-side applications. Now they have been adapted for JavaScript too.

As most JavaScript developers currently using these patterns opt to utilize various libraries or frameworks for implementing an MVC/MV*-like structure, we will compare how these solutions differ in their interpretation of MVC compared to classical takes on these patterns.

NOTE

You can easily distinguish the model and view layers in most modern browser-based UI design frameworks based on MVC/MVVM. However, the third

component varies in both name and function. The * in MV* thus represents whatever form the third component takes in the different frameworks.

MVC

MVC is an architectural design pattern that encourages improved application organization through a separation of concerns. It enforces the isolation of business data (Models) from user interfaces (Views), with a third component (Controllers) traditionally managing logic and user input. Trygve Reenskaug originally designed the pattern while working on Smalltalk-80 (1979), where it was initially called Model-View-Controller-Editor. MVC was later described in depth in 1995's *Design Patterns: Elements of Reusable Object-Oriented Software* a.k.a the “GoF” book, which played a role in popularizing its use.

Smalltalk-80 MVC

It's essential to understand what the original MVC pattern was aiming to solve, as it has mutated quite heavily since the days of its origin. Back in the 70s, graphical user interfaces were few and far between. A concept known as **Separated Presentation** became famous as a means to make a clear division between domain objects that modeled ideas in the real world (e.g., a photo, a person) and the presentation objects that were rendered to the users's screen.

The Smalltalk-80 implementation of MVC took this concept further and aimed to separate the application logic from the user interface. The idea was that decoupling these parts of the application would also allow the reuse of models for other interfaces in the application. There are some interesting points worth noting about Smalltalk-80's MVC architecture:

- A Model represented domain-specific data and was ignorant of the user interface (Views and Controllers). When a model changed, it would inform its observers.
- A View represented the current state of a Model. The Observer pattern

was used to let the View know whenever the Model was updated or modified.

- The View took care of the presentation, but there wasn't just a single View and Controller—a View-Controller pair was required for each section or element displayed on the screen.
- The Controller's role in this pair was handling user interaction (such as key presses and actions such as clicks) and making decisions for the View.

Developers are sometimes surprised when they learn that the Observer pattern (nowadays commonly implemented as the Publish/Subscribe variation) was included as a part of MVC's architecture many decades ago. In Smalltalk-80's MVC, the View observes the Model. As mentioned in the bullet point above, anytime the Model changes, the Views react. A simple example of this is an application backed by stock market data. For the application to be helpful, any change to the data in our Models should result in the View being refreshed instantly.

Martin Fowler has done an excellent job of writing about the origins of MVC over the years. If you are interested in some further historical information about Smalltalk-80's, I recommend reading his work.

MVC for JavaScript Developers

We've reviewed the 1970s, but let us return to the present. In modern times, the MVC pattern has been used with a diverse range of programming languages and application types, including of most relevance to us: JavaScript. JavaScript now has several frameworks boasting support for MVC (or variations of it, which we refer to as the MV* family), allowing developers to add structure to their applications easily.

The first among these frameworks include Backbone, Ember.js, and AngularJS. More recently, React, Angular and Vue.js ecosystems have been used to implement variations of the MV* family of patterns. Given the

importance of avoiding “spaghetti” code, a term that describes code that is very difficult to read or maintain due to its lack of structure, the modern JavaScript developer must understand what this pattern provides. This allows us to effectively appreciate what these frameworks enable us to do differently (Figure 8-1).

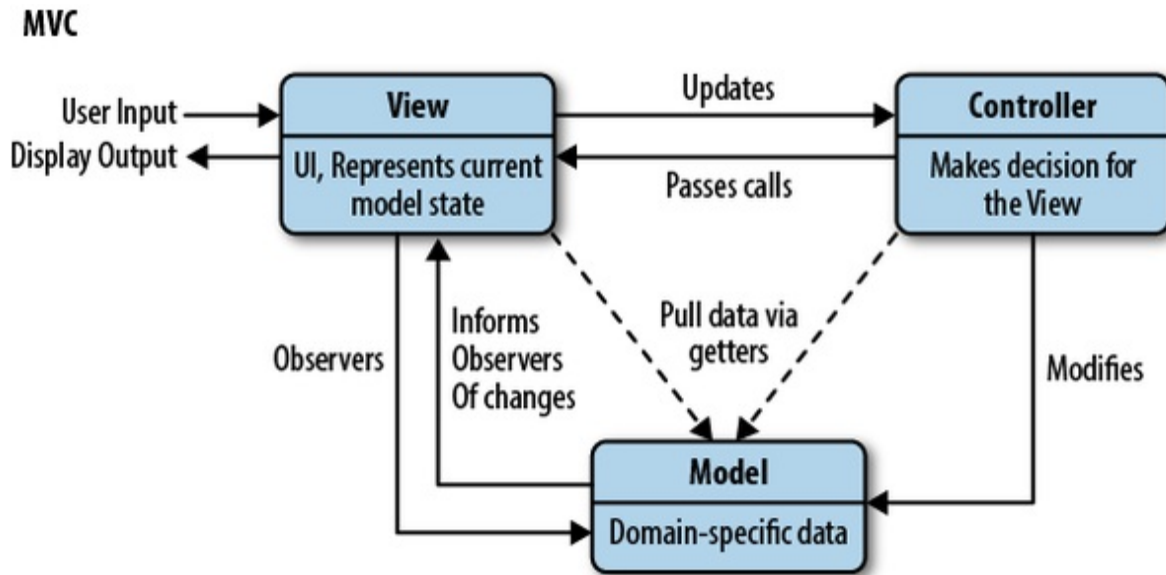

Figure 8-1. MVC pattern

MVC comprises three core components, described in the following sections.

Models

Models manage the data for an application. They are concerned with neither the user interface nor presentation layers but represent unique data forms that an application may require. When a model changes (e.g., when it is updated), it will typically notify its observers (e.g., views, a concept we will cover shortly) that a change has occurred so that it may react accordingly.

To understand models further, let us imagine we have a photo gallery application. In a photo gallery, the concept of a photo would merit its own model, as it represents a unique kind of domain-specific data. Such a model may contain related attributes such as a caption, image source, and additional metadata. You would store a specific photo in an instance of a model, and a model may also be reusable.

The built-in capabilities of models vary across frameworks. However, it is pretty standard for them to support the validation of attributes, where attributes represent the properties of the model, such as a model identifier. When using models in real-world applications, we generally also desire model persistence. Persistence allows us to edit and update models with the knowledge that their most recent state will be saved in either memory, local storage, or synchronized with a database.

In addition, a model may have multiple views observing it. If, say, our photo model contained metadata, such as its location (longitude and latitude), friends who were present in the photo (a list of identifiers), and a list of tags, a developer may decide to provide a single view to display each of these three facets.

It is not uncommon for MVC/MV* frameworks to provide a means to group models as a collection. Managing models in groups allows us to write application logic based on notifications from the group whenever any of the models in the group is changed. This avoids the need to observe individual model instances manually.

Older texts on MVC may also refer to a notion of models managing application *state*. In JavaScript applications, the *state* has a different connotation, typically referring to the current “state” — i.e., view or subview (with specific data) on a user’s screen at a fixed point. The state is regularly discussed when looking at single-page applications, where the concept of state needs to be simulated.

So to summarize, models are primarily concerned with business data.

Views

Views are a visual representation of models that present a filtered view of their current state. While Smalltalk views are about painting and maintaining a bitmap, JavaScript views build and organize a collection of DOM elements.

A view typically observes a model and is notified when the model changes, allowing the view to update itself accordingly. Design pattern literature

commonly refers to views as “dumb,” given that their knowledge of models and controllers in an application is limited.

Users can interact with views, including the ability to read and edit (i.e., get or set the attribute values in) models. As the view is the presentation layer, we generally present the ability to edit and update in a user-friendly fashion. For example, in the photo gallery application we discussed earlier, we could facilitate model editing through an “edit” view where a user who selected a specific photo could edit its metadata.

The actual task of updating the model falls to the controllers (which we will cover shortly).

Let’s explore views a little further using a vanilla JavaScript sample implementation. Below we can see a function that creates a single photo view, consuming both a model and a controller instance.

We define a `render ()` utility within our view, which is responsible for rendering the contents of the `photoModel` using a JavaScript templating engine (Underscore templating) and updating the contents of our view, referenced by `photoEl`.

The `photoModel` then adds our `render ()` callback as one of its subscribers so that we can trigger the view to update when the model changes using the Observer pattern.

One may wonder where user interaction comes into play here. When users click on any element within the view, it’s not the view’s responsibility to know what to do next. It relies on a controller to make this decision for it. Our sample implementation achieves this by adding an event listener to `photoEl`, which will delegate handling the click behavior back to the controller, passing the model information along with it in case it’s needed.

The architecture’s benefit is that each component plays its role in making the application function as needed.

```
const buildPhotoView = (photoModel, photoController) => {  
  const base = document.createElement( "div" );  
  const photoEl = document.createElement( "div" );
```

```

base.appendChild(photoEl);

const render = () => {
  // We use a templating library such as Underscore
  // templating which generates the HTML for our
  // photo entry
  photoEl.innerHTML = _.template( "#photoTemplate"
, {
    src: photoModel.getSrc()
  });

photoModel.addSubscriber( render );

photoEl.addEventListener( "click", () => {
  photoController.handleEvent( "click", photoModel );
});

const show = () => {
  photoEl.style.display = "";
};

const hide = () => {
  photoEl.style.display = "none";
};

return {
  showView: show,
  hideView: hide
};
};

```

Templating

It would be worthwhile to briefly touch upon JavaScript templating while discussing JavaScript frameworks that support MVC/MV*. As mentioned in the previous section, templating is related to views.

It has long been considered (and proven) a performance-bad practice to manually create large blocks of HTML markup in memory through string

concatenation. Developers have fallen prey to inefficient iterations through their data, wrapping it in nested `divs` and using outdated techniques such as `document.write` to inject the generated “template” into the DOM. This typically means including scripted markup inline with our standard markup. The markup can quickly become difficult to read, and, more importantly, a non-trivial application with such code can be a maintenance disaster.

JavaScript templating solutions (such as Handlebars.js and Mustache) are often used to define templates for views as markup (either stored externally or within script tags with a custom type—e.g., `text/template`) containing template variables. Variables may be delimited using a variable syntax (e.g., `{{name}}`). Frameworks are typically smart enough to accept data in JSON form, and model instances can be converted to JSON form. Thus we only need to be concerned with maintaining clean models and templates. The framework takes care of most of the grunt work for populating templates from models. This has many benefits, particularly when opting to store templates externally. This can give way to templates being dynamically loaded on an as-needed basis when building larger applications.

Here, we can see two examples of HTML templates (Examples 8-1 and 8-2). One has been implemented using the Handlebars.js framework, and another using Underscore’s templates.

Example 8-1. Handlebars.js code

```
<li class="photo">
  <h2>{{caption}}</h2>
  
  <div class="meta-data">
    {{metadata}}
  </div>
</li>
```

Example 8-2. Underscore.js Microtemplates

```
<li class="photo">
  <h2><%= caption %></h2>
  
  <div class="meta-data">
    <%= metadata %>
  </div>
</li>
```

```
</div>  
</li>
```

Note that templates are not themselves views. A view is an object that observes a model and keeps the visual representation up to date. A template *might* be a declarative way to specify part or even all of a view object so that the framework may generate it from the template specification.

It is also worth noting that in classical web development, navigating between independent views required the use of a page refresh. In single-page JavaScript applications, however, once data is fetched from a server, it can be dynamically rendered in a new view within the same page without any such refresh being necessary. The navigation role thus falls to a router, which assists in managing application state (e.g., allowing users to bookmark a particular view they have navigated to). However, as routers are neither a part of MVC nor present in every MVC-like framework, I will not be going into them in greater detail in this section.

To summarize, views represent our application data visually, and templates may be used to generate views.

Controllers

Controllers are intermediaries between models and views, which are classically responsible for updating the model when the user manipulates the view. They manage the logic and coordination between models and views in an application.

What Does MVC Give Us?

This separation of concerns in MVC facilitates simpler modularization of an application's functionality and enables:

- Easier overall maintenance. When the application needs to be updated, it is obvious whether the changes are data-centric, meaning changes to models and possibly controllers, or merely visual, meaning changes to

views.

- Decoupling models and views means that writing unit tests for business logic is significantly more straightforward.
- Duplication of low-level model and controller code (i.e., what we may have been using instead) is eliminated across the application.
- Depending on the size of the application and the separation of roles, this modularity allows developers responsible for core logic and developers working on the user interfaces to work simultaneously.

Smalltalk-80 MVC in JavaScript

Most modern-day JavaScript frameworks attempt to evolve the MVC paradigm to fit the differing needs of web application development. However, there has been one framework that tried to adhere to the pure form of the pattern found in Smalltalk-80. Maria.js (<https://github.com/petermichaux/maria>) by Peter Michaux offers an implementation that is faithful to MVC's origins: Models are models, Views are views, and Controllers are nothing but controllers. While some developers might feel an MV* framework should address more concerns, this is a valuable reference to be aware of in case you would like a JavaScript implementation of the original MVC.

AN ALTERNATE VIEW OF MVC

At this point in the book, we should have a basic understanding of the MVC pattern, but there's still some fascinating information about it worth noting.

The GoF (Gang of Four) The GoF does not refer to MVC as a design pattern but considers it *a set of classes to build a user interface*. In their view, it's a variation of three classical design patterns: the Observer, Strategy, and Composite patterns. Depending on how MVC has been implemented in a framework, it may also use the Factory and Template

patterns. The GoF book mentions these patterns as useful extras when working with MVC.

As we have discussed, models represent application data, while views represent what the user is presented with on screen. As such, MVC relies on the Observer pattern for some of its core communication (something that, surprisingly, isn't covered in many articles about the MVC pattern). When a model is changed, it notifies its observers (Views) that something has been updated—this is perhaps the most crucial relationship in MVC. The observer nature of this relationship also facilitates multiple views being attached to the same model.

For developers interested in the decoupled nature of MVC, one of the goals of the pattern is to help define one-to-many relationships between a topic and its observers. When a topic changes, its observers are updated. Views and controllers have a slightly different relationship. Controllers facilitate views to respond to user input and are an example of the Strategy pattern.

Summary

Having reviewed the classical MVC pattern, we should now understand how it allows us to cleanly separate concerns in an application. We should also appreciate how JavaScript MVC frameworks may differ in their interpretation of the MVC pattern. Although quite open to variation, they still share some fundamental concepts the original pattern offers.

When reviewing a new JavaScript MVC/MV* framework, remember: it can be helpful to step back and examine how it has opted to approach the architecture (specifically, how it supports implementing models, views, controllers, or other alternatives), as this can better help us grok the best way to use the framework.

MVP

Model View Presenter (MVP) is a derivative of the MVC design pattern that focuses on improving presentation logic. It originated at a company named **Taligent** in the early 1990s while they were working on a model for a C++ CommonPoint environment. While both MVC and MVP target the separation of concerns across multiple components, there are some fundamental differences between them.

Here, we will focus on the version of MVP most suitable for web-based architectures.

Models, Views, and Presenters

The P in MVP stands for presenter. It's a component that contains the user-interface business logic for the view. Unlike MVC, invocations from the view are delegated to the presenters, that are decoupled from the view and instead talk to it through an interface. This has many advantages, such as being able to mock views in unit tests (MVP pattern)(**Figure 8-2**).

MVP

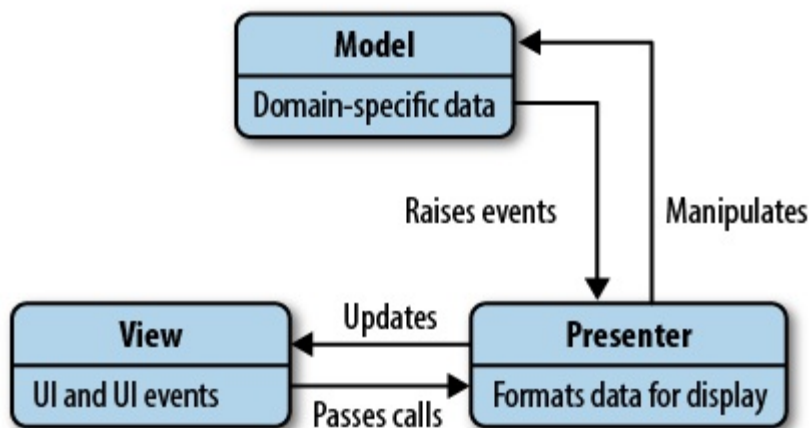

Figure 8-2. MVP pattern

The most common implementation of MVP is one that uses a Passive View (a view which is, for all intents and purposes, “dumb”), containing little to no logic. MVC and MVP are different because the roles played by C and P are diverse. In MVP, the P observes models and updates views when models change. The P effectively binds models to views, a controller’s responsibility

in MVC.

Solicited by a view, presenters perform any work related to user requests and pass data back to them. In this respect, they retrieve data, manipulate it, and determine how the data should be displayed in the View. In some implementations, the Presenter also interacts with a service layer to persist data (models). Models may trigger events, but it's the Presenter's role to subscribe to them so that it can update the View. In this passive architecture, we have no concept of direct data binding. Views expose setters that presenters can use to set data.

The benefit of this change from MVC is that it increases our application's testability and provides a cleaner separation between the View and the model. This isn't, however, without its costs, as the lack of data-binding support in the pattern can often mean having to take care of this task separately.

Although a common implementation of a <http://martinfowler.com/eaaDev/PassiveScreen.xhtml> [Passive View] is for the View to implement an interface, there are variations on it, including the use of events that can decouple the View from the Presenter a little more. As we don't have the interface construct in JavaScript, we use more of a protocol than an explicit interface here. It's technically still an API, and it's probably fair for us to refer to it as an interface from that perspective.

There is also a **Supervising Controller** variation of MVP, closer to the MVC and **MVVM** patterns, as it provides data-binding from the Model directly from the View.

MVP or MVC?

Now that we've discussed both MVP and MVC, how do you select the most appropriate pattern for your application?

MVP is generally used in enterprise-level applications where it's necessary to reuse as much presentation logic as possible. Applications with very complex views and a great deal of user interaction may find that MVC doesn't quite fit the bill here, as solving this problem may mean heavily relying on multiple

controllers. In MVP, all of this complex logic can be encapsulated in a presenter, significantly simplifying maintenance.

As MVP views are defined through an interface, and the interface is technically the only point of contact between the system and the View (other than a presenter), this pattern also allows developers to write presentation logic without needing to wait for designers to produce layouts and graphics for the application.

MVP may be easier to unit test than MVC, depending on the implementation. The reason often cited for this is that you can use the Presenter as a complete mock of the user interface so it can be unit-tested independent of other components. In my experience, this depends on the languages we are implementing MVP in (there's quite a difference between opting for MVP for a JavaScript project over one for, say, ASP.NET).

The underlying concerns we may have with MVC will likely hold for MVP, given that the differences between them are mainly semantic. As long as we cleanly separate concerns into models, views, and controllers (or presenters), we should achieve most of the same benefits regardless of the variation we choose.

Very few, if any, JavaScript architectural frameworks claim to implement the MVC or MVP patterns in their classical form. Many JavaScript developers don't view MVC and MVP as mutually exclusive (we are more likely to see MVP strictly implemented in web frameworks such as ASP.NET or GWT). This is because we can have additional presenter/view logic in our application and still consider it a flavor of MVC.

MVVM

MVVM (Model View ViewModel) is an architectural pattern based on MVC and MVP, which attempts to more clearly separate the development of user interfaces (UI) from that of the business logic and behavior in an application. To this end, many implementations of this pattern make use of declarative data bindings to allow a separation of work on Views from other layers.

This facilitates UI and development work occurring almost simultaneously within the same code base. UI developers write bindings to the ViewModel within their document markup (HTML), whereas developers working on the logic for the application maintain the Model and ViewModel (Figure 8-3).

MVVM

Figure 8-3. MVVM pattern

History

MVVM (by name) was initially defined by Microsoft for use with Windows Presentation Foundation (WPF) and Silverlight, having been officially announced in 2005 by John Grossman in a blog post about Avalon (the codename for WPF). It also found some popularity in the Adobe Flex community as an alternative to using MVC.

Before Microsoft adopted the MVVM name, there was a movement in the community to go from MVP to MVPM: Model View **PresentationModel**. Martin Fowler wrote an **article** on PresentationModels back in 2004 for those interested in reading more about it. The idea of a **PresentationModel** had been around much longer than this article. However, it was considered a significant break for the concept and helped popularize it.

There was quite a lot of uproar in the “alt.net” circles after Microsoft announced MVVM as an alternative to MVPM. Many claimed the company’s dominance in the GUI world allowed them to take over the

community, renaming existing concepts as they pleased for marketing purposes. A progressive crowd recognized that while MVVM and MVP were effectively the same ideas, they came in slightly different packages.

MVVM was originally implemented in JavaScript in the form of structural frameworks such as KnockoutJS, Kendo MVVM, and Knockback.js, with an overall positive response from the community.

Let's now review the three components that compose MVVM.

- **Model:** Representing the domain-specific information.
- **View:** The user interface.
- **ViewModel:** An interface between the model and the view.

Model

As with other members of the MV* family, the Model in MVVM represents domain-specific data or information with which our application will work. A typical example of domain-specific data might be a user account (e.g., name, avatar, email) or a music track (e.g., title, year, album).

Models hold information but typically don't handle behavior. They don't format information or influence how data appears in the browser, as this isn't their responsibility. Instead, the View governs data formatting, while the behavior is considered business logic that you should encapsulate in another layer that interacts with the Model: the ViewModel.

The only exception to this rule tends to be validation, and it's acceptable for Models to validate data used to define or update existing models (e.g., does an email address being input meet the requirements of a particular regular expression?).

View

As with MVC, the View is the only part of the application that users interact with. They are an interactive UI that represents the state of a ViewModel. In

this sense, the View is considered active rather than passive, which is also true for MVC and MVP views. In MVC, MVP, and MVVM, a View can also be passive, but what does this mean?

A passive View only outputs a display and does not accept any user input. Such a view may also have no real knowledge of the models in our application and could be manipulated by a presenter. MVVM's active View contains the data bindings, events, and behaviors, which requires an understanding of the ViewModel. Although these behaviors can be mapped to properties, the View is still responsible for handling events from the ViewModel.

It's important to remember that the View isn't responsible for handling state; it keeps this in sync with the ViewModel.

ViewModel

The ViewModel can be considered a specialized Controller that acts as a data converter. It changes Model information into View information, passing commands from the View to the Model.

For example, let us imagine that we have a model containing a `date` attribute in UNIX format (e.g., 1333832407). Rather than our models being aware of a user's View of the date (e.g., 04/07/2012 @ 5:00 pm), where it would be necessary to convert the address to its display format, our Model holds the raw format of the data. Our View contains the formatted date, and our ViewModel acts as a middleman between the two.

In this sense, the ViewModel can be seen as more of a Model than a View, but it does handle most of the View's display logic. The ViewModel may also expose methods for helping to maintain the View's state, update the Model based on the actions on a View, and trigger events on the View.

In summary, the ViewModel sits behind our UI layer. It exposes data needed by a View (from a Model) and can be the source the View goes to for both data and actions.

Recap: The View and the ViewModel

Views and ViewModels communicate using data bindings and events. As we saw in our initial ViewModel example, the ViewModel doesn't just expose Model attributes but also provides access to other methods and features, such as validation.

Our Views handle their own user interface events, mapping them to the ViewModel as necessary. Models and attributes on the ViewModel are synchronized and updated via two-way data binding.

Triggers (data triggers) also allow us to react further to changes in the state of our Model attributes.

ViewModel Vs. Model

While the ViewModel may be entirely responsible for the Model in MVVM, there are some subtleties with this relationship worth noting. The ViewModel can expose a Model or Model attributes for data binding and contain interfaces for fetching and manipulating properties exposed in the view.

Pros and Cons

We now hopefully have a better appreciation for what MVVM is and how it works. Let's now review the advantages and disadvantages of employing the pattern.

Advantages

- MVVM facilitates easier parallel development of a UI and the building blocks that power it.
- MVVM abstracts the View and thus reduces the quantity of business logic (or glue) required in the code behind it.
- The ViewModel can be easier to unit test than in the case of event-

driven code.

- The ViewModel (being more Model than View) can be tested without UI automation and interaction concerns.

Disadvantages

- For simpler UIs, MVVM can be overkill.
- While data bindings can be declarative and nice to work with, they can be harder to debug than imperative code, where we simply set breakpoints.
- Data bindings in nontrivial applications can create a lot of bookkeeping. We also don't want to end up in a situation where bindings are heavier than the objects being bound.
- In larger applications, it can be more challenging to design the ViewModel up front to get the necessary generalization.

MVC Versus MVP Versus MVVM

Both MVP and MVVM are derivatives of MVC. The key difference between MVC and its derivatives is the dependency each layer has on other layers, and how tightly bound they are to each other.

In MVC, the View sits on top of our architecture with the controller beside it. Models sit below the controller, so our Views know about our controllers, and controllers know about Models. Here, our Views have direct access to Models. Exposing the complete Model to the View, however, may have security and performance costs, depending on the complexity of our application. MVVM attempts to avoid these issues.

In MVP, the role of the controller is replaced with a Presenter. Presenters sit at the same level as views, listening to events from both the View and Model and mediating the actions between them. Unlike MVVM, there isn't a mechanism for binding Views to ViewModels, so we instead rely on each

View implementing an interface allowing the Presenter to interact with the View.

MVVM consequently allows us to create View-specific subsets of a Model, which can contain state and logic information, avoiding exposing the entire Model to a View. Unlike MVP's Presenter, a ViewModel is not required to reference a View. The View can bind to properties on the ViewModel, in turn exposing data contained in Models to the View. As we've mentioned, the abstraction of the View means there is less logic required in the code behind it.

However, one of the downsides to this is that a level of interpretation is needed between the ViewModel and the View, which can have performance costs. The complexity of this interpretation can also vary: it can be as simple as copying data or as complex as manipulating it to a form we would like the View to see. MVC doesn't have this problem, as the whole Model is readily available, and such manipulation can be avoided.

Modern MV* patterns

Frameworks such as Backbone and KnockoutJS used initially to implement MVC and MVVM, are no longer popular or updated. They have made way for other libraries and frameworks such as React, Vue.js, Angular, Solid, and many others. Understanding architecture from a Backbone or KnockoutJS perspective may still be relevant because it gives us a sense of where we came from and what changed with modern frameworks.

MV* patterns can always be implemented using the latest vanilla JavaScript as illustrated by this example of a list:<https://github.com/1Marc/modern-todomvc-vanillajs>[ToDo list MVC] application. However, developers generally prefer libraries and frameworks for building larger, scalable applications.

Technically modern libraries and frameworks such as React or Vue.js form the View or the presentation layer of applications. In most cases, the frameworks are flexible about how you implement your model and manage

the state in your applications. Vue officially claims to be the **ViewModel** layer in MVVM. Here are some additional thoughts on MV* in React.

MV* and React.js

To be very clear, React is not an MVC (Model-View-Controller) framework. It is a JavaScript library for building user interfaces and is often used for creating single-page applications.

React isn't considered MVC because it doesn't map well with how it has been conceived and used on the backend. React is a rendering library that ideally takes care of the View layer. It doesn't have a central Controller as an orchestrator/router, similar to MVC.

React follows a declarative approach to programming—you describe your application's desired state, and React renders the appropriate views based on that state. You don't use React in an MVC design pattern simply because, with React, the server does not provide a “view” to the browser but “data”. React parses the data on the browser to generate the actual views. In this sense, you could say that React is a “V” (View) in the MVC pattern, but it is not an MVC framework in the traditional sense.

Another way of looking at it is that React slices the MVC vertically (by concern) instead of horizontally (by technology). You could say Components in React started as small vertically-sliced encapsulated MVCs: containing state (model), rendering (view), and control-flow logic (a localized mini-controller).

These days, with a lot of component logic extracted into Hooks, you can see Components as Views and Hooks as Controllers. As Ryan Florence and Swizec Teller have **noted**. You can also consider “Model \Rightarrow Suspense resource, View \Rightarrow Component, Controller \Rightarrow Hook” if it helps but don't take it too seriously.

Next.js is a framework built on top of React that makes it easy to construct server-rendered React applications. It includes features such as automatic code splitting, optimized performance, and easy deployment to production.

Like React, Next.js is not an MVC framework, but when you use Server Side Rendering (SSR) or Static Site Generation (SSG), it can be like MVC. When Next.js acts as a backend, interacting with a Database and providing the view to pre-render it, then yes, it's MVC that is hydrated afterward with the reactive functionalities.

Summary

We have now analyzed the concepts of Model, View, Controller, Presenter, and ViewModel and where they fit in different architectural patterns. Today, we may not see these patterns applied as-is on the front end where JavaScript is most relevant. However, they may help us figure out the overall architecture of the web application. They may also be applied to individual frontend components where the application sliced vertically may have multiple components, each with a ViewModel or Model to power the View.

We have now covered a good mix of patterns at the micro(class) as well as macro(architecture) levels. The next chapter will help us design the application flow for a modern JavaScript application. We will look at asynchronous programming patterns that can help us better manage long-running tasks on browsers.

Chapter 9. Asynchronous Programming Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 9th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

Asynchronous JavaScript programming allows you to execute long-running tasks in the background while allowing the browser to respond to events and run other code to handle these events. Asynchronous programming is relatively new in JavaScript, and the syntax to support it was not available when the first edition of this book was published.

JavaScript concepts such as `promise`, `async`, and `await` make your code tidier and easy to read without blocking the main thread. Async functions were introduced as part of ES7 in 2016 and are now supported on all browsers. So let us look at some patterns that use these features to structure our application flows.

Async Programming

In JavaScript, synchronous code is executed in a blocking manner, meaning that the code is executed serially, one statement at a time. The following code

can run only after the execution of the current statement has been completed. When you call a synchronous function, the code inside that function will execute from start to finish before the control returns to the caller.

On the other hand, asynchronous code is executed in a non-blocking manner, meaning that the JavaScript engine can switch to execute this code in the background while the currently running code is waiting on something. When you call an asynchronous function, the code inside the function will execute in the background, and the control returns to the caller immediately.

Here is an example of synchronous code in JavaScript:

```
function synchronousFunction() {  
    // do something  
}  
  
synchronousFunction();  
// the code inside the function is executed before this line
```

And here is an example of asynchronous code in JavaScript:

```
function asynchronousFunction() {  
    // do something  
}  
  
asynchronousFunction();  
// the code inside the function is executed in the background while control returns to this line
```

You can generally use asynchronous code to perform long-running operations without blocking the rest of your code. Asynchronous code is suitable when making network requests, reading or writing to a database, or doing any other type of I/O (input/output) operation.

Language features such as `async`, `await`, and `promise` make writing asynchronous code in JavaScript easier. They allow you to write asynchronous code in a way that looks and behaves like synchronous code, making it easier to read and understand.

Let's briefly look at the differences between callbacks, promises, and async/await before diving into each in more depth.

```
// using callbacks
function makeRequest(url, callback) {
  fetch(url)
    .then(response => response.json())
    .then(data => callback(null, data))
    .catch(error => callback(error));
}

makeRequest('http://example.com/', (error, data) => {
  if (error) {
    console.error(error);
  } else {
    console.log(data);
  }
}));
```

In the first example, the `makeRequest` function uses a callback to return the result of the network request. The caller passes a `callback` function to `makeRequest`, which is called back with either the `result(data)` or an `error`.

```
// using promises
function makeRequest(url) {
  return new Promise((resolve, reject) => {
    fetch(url)
      .then(response => response.json())
      .then(data => resolve(data))
      .catch(error => reject(error));
  }));
}

makeRequest('http://example.com/')
  .then(data => console.log(data))
  .catch(error => console.error(error));
```

In the second example, the `makeRequest` function returns a `promise` that resolves with the result of the network request or rejects with an error. The

caller can use the `then` and `catch` methods on the returned promise to handle the result of the request.

```
// using async/await
async function makeRequest(url) {
  try {
    const response = await fetch(url);
    const data = await response.json();
    console.log(data);
  } catch (error) {
    console.error(error);
  }
}

makeRequest('http://example.com/');
```

In the third example, the `makeRequest` function is declared with the `async` keyword, which allows it to use the `await` keyword to wait for the result of the network request. The caller can use the `try` and `catch` keywords to handle any errors that may occur during the execution of the function.

Background

Callback functions in JavaScript can be passed to another function as an argument and executed after some asynchronous operation is completed. Callbacks were commonly used to handle the results of asynchronous operations, such as network requests or user input.

One of the main disadvantages of using callbacks is that they can lead to what is known as “callback hell” – a situation where nested callbacks become challenging to read and maintain. Consider the following example:

```
function makeRequest1(url, callback) {
  // make network request
  callback(null, response);
}

function makeRequest2(url, callback) {
```

```

    // make network request
    callback(null, response);
}

function makeRequest3(url, callback) {
    // make network request
    callback(null, response);
}

makeRequest1('http://example.com/1', (error, data1) => {
    if (error) {
        console.error(error);
        return;
    }

    makeRequest2('http://example.com/2', (error, data2) => {
        if (error) {
            console.error(error);
            return;
        }

        makeRequest3('http://example.com/3', (error, data3) =>
        {
            if (error) {
                console.error(error);
                return;
            }

            // do something with data1, data2, data3
        });
    });
});

```

In this example, the `makeRequest1` function makes a network request and then calls the `callback` function with the result of the request. The `callback` function then makes a second network request using the `makeRequest2` function, which calls another `callback` function with its result. This pattern continues for the third network request.

Promise Patterns

Promises are a more modern approach to handling asynchronous operations in JavaScript. A promise is an object that represents the result of an asynchronous operation. It can be in three states: pending, fulfilled, or rejected. A promise is like a contract that can be settled if it is fulfilled or rejected.

You can create a promise using the Promise constructor, which takes a function as an argument. The function receives two arguments: resolve and reject. The resolve function is called when the asynchronous operation is completed successfully, and the reject function is called if the operation fails.

Here is an example that shows how you can use promises to make network requests:

```
function makeRequest(url) {  
  return new Promise((resolve, reject) => {  
    fetch(url)  
      .then(response => response.json())  
      .then(data => resolve(data))  
      .catch(error => reject(error));  
  });  
}  
  
makeRequest('http://example.com/')  
  .then(data => console.log(data))  
  .catch(error => console.error(error));
```

In this example, the makeRequest function returns a promise representing the network request's result. The fetch method is used inside the function to make the HTTP request. If the request succeeds, the promise is fulfilled with the data from the response. If it fails, the promise is rejected with the error. The caller can use the then and catch methods on the returned promise to handle the result of the request.

One of the main advantages of using promises over callbacks is that they provide a more structured and readable approach to handling asynchronous operations. This allows you to avoid “callback hell” and write code that is

easier to understand and maintain.

The following sections provide additional examples that will be relevant to help you understand the different promise design patterns that you can use in JavaScript.

Promise Chaining

This pattern allows you to chain multiple promises together to create more complex async logic.

```
function makeRequest(url) {
  return new Promise((resolve, reject) => {
    fetch(url)
      .then(response => response.json())
      .then(data => resolve(data))
      .catch(error => reject(error));
  });
}

function processData(data) {
  // process data
  return processedData;
}

makeRequest('http://example.com/')
  .then(data => processData(data))
  .then(processedData => console.log(processedData))
  .catch(error => console.error(error));
```

Promise Error Handling

This pattern uses the catch method to handle errors that may occur during the execution of a promise chain.

```
makeRequest('http://example.com/')
  .then(data => processData(data))
  .then(processedData => console.log(processedData))
  .catch(error => console.error(error));
```

Promise Parallelism

This pattern allows you to run multiple promises concurrently using the `Promise.all` method.

```
Promise.all([
  makeRequest('http://example.com/1'),
  makeRequest('http://example.com/2')
]).then(([data1, data2]) => {
  console.log(data1, data2);
});
```

Promise Sequential Execution

This pattern allows you to run promises in sequence using the `Promise.resolve` method.

```
Promise.resolve()
  .then(() => makeRequest1())
  .then(() => makeRequest2())
  .then(() => makeRequest3())
  .then(() => {
    // all requests completed
  });
```

Promise Memoization

This pattern uses a cache to store the results of promise function calls, allowing you to avoid making duplicate requests.

```
const cache = new Map();

function memoizedMakeRequest(url) {
  if (cache.has(url)) {
    return cache.get(url);
  }

  return new Promise((resolve, reject) => {
```

```

    fetch(url)
    .then(response => response.json())
    .then(data => {
      cache.set(url, data);
      resolve(data);
    })
    .catch(error => reject(error));
  });
}

```

Promise Memoization

This pattern uses a cache to store the results of promise function calls, allowing you to avoid making duplicate requests.

```

const button = document.querySelector('button');

button.addEventListener('click', () => {
  makeRequest('http://example.com/')
    .then(data => console.log(data))
    .catch(error => console.error(error));
});

```

Promise Pipeline

This pattern uses promises and functional programming techniques to create a pipeline of async transformations.

```

function transform1(data) {
  // transform data
  return transformedData;
}

function transform2(data) {
  // transform data
  return transformedData;
}

makeRequest('http://example.com/')
  .then(data => pipeline(data))

```

```

    .then(transform1)
    .then(transform2))
  .then(transformedData => console.log(transformedData))
  .catch(error => console.error(error));

```

Promise Retry

This pattern allows you to retry a promise if it fails.

```

function makeRequestWithRetry(url) {
  let attempts = 0;

  const makeRequest = () => new Promise((resolve, reject)
=> {
    fetch(url)
      .then(response => response.json())
      .then(data => resolve(data))
      .catch(error => reject(error));
  }));

  const retry = error => {
    attempts++;
    if (attempts >= 3) {
      throw new Error('Request failed after 3 attempts.');
```

Promise Decorator

This pattern uses a higher-order function to create a decorator that can be applied to promises to add additional behavior.

```

function logger(fn) {
  return function (...args) {
    console.log('Starting function...');

```

```

        return fn(...args).then(result => {
            console.log('Function completed.');
```

```

            return result;
        });
    };
}

const makeRequestWithLogger = logger(makeRequest);

makeRequestWithLogger('http://example.com/')
    .then(data => console.log(data))
    .catch(error => console.error(error));
```

Promise Race

This pattern allows you to run multiple promises concurrently and return the result of the first one to settle.

```

Promise.race([
    makeRequest('http://example.com/1'),
    makeRequest('http://example.com/2')
]).then(data => {
    console.log(data);
});
```

Async/Await Patterns

Async/await is a language feature that allows a programmer to write asynchronous code as if it were synchronous. It is built on top of promises, and it makes working with asynchronous code easier and cleaner.

Here is an example of how you might use async/await to make an asynchronous HTTP request:

```

async function makeRequest() {
    try {
        const response = await fetch('http://example.com/');
        const data = await response.json();
        console.log(data);
    }
}
```

```
    } catch (error) {  
      console.error(error);  
    }  
  }  
}
```

In this example, the `makeRequest` function is asynchronous because it uses the `async` keyword. Inside the function, the `await` keyword is used to pause the execution of the function until the `fetch` call resolves. If the call succeeds, the data is logged to the console. If it fails, the error is caught and logged to the console.

Let us now look at some other patterns using `async`.

Async Function Composition

This pattern involves composing multiple `async` functions together to create more complex `async` logic.

```
async function makeRequest(url) {  
  const response = await fetch(url);  
  const data = await response.json();  
  return data;  
}  
  
async function processData(data) {  
  // process data  
  return processedData;  
}  
  
async function main() {  
  const data = await makeRequest('http://example.com/');  
  const processedData = await processData(data);  
  console.log(processedData);  
}
```

Async Iteration

This pattern allows you to use the `for-await-of` loop to iterate over an `async` iterable.

```

async function* createAsyncIterable() {
  yield 1;
  yield 2;
  yield 3;
}

async function main() {
  for await (const value of createAsyncIterable()) {
    console.log(value);
  }
}

```

Async Error Handling

This pattern uses try-catch blocks to handle errors that may occur during the execution of an async function.

```

async function main() {
  try {
    const data = await makeRequest('http://example.com/');
    console.log(data);
  } catch (error) {
    console.error(error);
  }
}

```

Async Parallelism

This pattern allows you to run multiple async tasks concurrently using the `Promise.all` method.

```

async function main() {
  const [data1, data2] = await Promise.all([
    makeRequest('http://example.com/1'),
    makeRequest('http://example.com/2')
  ]);

  console.log(data1, data2);
}

```

Async Sequential Execution

This pattern allows you to run async tasks in sequence using the `Promise.resolve` method.

```
async function main() {  
  let result = await Promise.resolve();  
  
  result = await makeRequest1(result);  
  result = await makeRequest2(result);  
  result = await makeRequest3(result);  
  
  console.log(result);  
}
```

Async Memoization

This pattern uses a cache to store the results of async function calls, allowing you to avoid making duplicate requests.

```
const cache = new Map();  
  
async function memoizedMakeRequest(url) {  
  if (cache.has(url)) {  
    return cache.get(url);  
  }  
  
  const response = await fetch(url);  
  const data = await response.json();  
  
  cache.set(url, data);  
  return data;  
}
```

Async Event Handling

This pattern allows you to use async functions to handle events.

```
const button = document.querySelector('button');
```

```
async function handleClick() {
  const response = await
  makeRequest('http://example.com/');
  console.log(response);
}

button.addEventListener('click', handleClick);
```

Async/await Pipeline

This pattern uses async/await and functional programming techniques to create a pipeline of async transformations.

```
async function transform1(data) {
  // transform data
  return transformedData;
}

async function transform2(data) {
  // transform data
  return transformedData;
}

async function main() {
  const data = await makeRequest('http://example.com/');
  const transformedData = await pipeline(data)
    .then(transform1)
    .then(transform2);

  console.log(transformedData);
}
```

Async Retry

This pattern allows you to retry an async operation if it fails.

```
async function makeRequestWithRetry(url) {
  let attempts = 0;

  while (attempts < 3) {
```

```

    try {
      const response = await fetch(url);
      const data = await response.json();
      return data;
    } catch (error) {
      attempts++;
      console.log(`Retrying request: attempt ${attempts}`);
    }
  }

  throw new Error('Request failed after 3 attempts.');
```

Async/await Decorator

This pattern uses a higher-order function to create a decorator that can be applied to async functions to add additional behavior.

```

function asyncLogger(fn) {
  return async function (...args) {
    console.log('Starting async function...');
    const result = await fn(...args);
    console.log('Async function completed.');
```

```

    return result;
  };
}

@asyncLogger
async function main() {
  const data = await makeRequest('http://example.com/');
  console.log(data);
}
```

Additional Practical Examples

In addition to the patterns discussed in the previous sections, let us now look at some practical examples of using async/await in JavaScript:

Making an HTTP Request

```

async function makeRequest(url) {
  try {
    const response = await fetch(url);
    const data = await response.json();
    console.log(data);
  } catch (error) {
    console.error(error);
  }
}

```

Reading a File from the File System

```

async function readFile(filePath) {
  try {
    const fileData = await fs.promises.readFile(filePath);
    console.log(fileData);
  } catch (error) {
    console.error(error);
  }
}

```

Writing to a File on the File System:

```

async function writeFile(filePath, data) {
  try {
    await fs.promises.writeFile(filePath, data);
    console.log('File written successfully.');
```

Executing Multiple async Operations

```

async function main() {
  try {
    const [data1, data2] = await Promise.all([
      makeRequest1(),
      makeRequest2()
    ])
  }
}

```

```

    ]);
    console.log(data1, data2);
  } catch (error) {
    console.error(error);
  }
}

```

Executing Multiple async Operations in Sequence

```

async function main() {
  try {
    const data1 = await makeRequest1();
    const data2 = await makeRequest2();
    console.log(data1, data2);
  } catch (error) {
    console.error(error);
  }
}

```

Caching the Result of an async Operation

```

const cache = new Map();

async function makeRequest(url) {
  if (cache.has(url)) {
    return cache.get(url);
  }

  try {
    const response = await fetch(url);
    const data = await response.json();
    cache.set(url, data);
    return data;
  } catch (error) {
    throw error;
  }
}

```

Handling Events with async/await

```

const button = document.querySelector('button');

button.addEventListener('click', async () => {
  try {
    const data = await makeRequest('http://example.com/');
    console.log(data);
  } catch (error) {
    console.error(error);
  }
});

```

Retrying an async Operation on Failure

```

async function makeRequest(url) {
  try {
    const response = await fetch(url);
    const data = await response.json();
    return data;
  } catch (error) {
    throw error;
  }
}

async function retry(fn, maxRetries = 3, retryDelay = 1000)
{
  let retries = 0;

  while (retries <= maxRetries) {
    try {
      return await fn();
    } catch (error) {
      retries++;
      console.error(error);
      await new Promise(resolve => setTimeout(resolve,
retryDelay));
    }
  }

  throw new Error(`Failed after ${retries} retries.`);
}

```

```
retry(() => makeRequest('http://example.com/')).then(data
=> {
  console.log(data);
});
```

Creating an async/await decorator

```
function asyncDecorator(fn) {
  return async function(...args) {
    try {
      return await fn(...args);
    } catch (error) {
      throw error;
    }
  };
}

const makeRequest = asyncDecorator(async function(url) {
  const response = await fetch(url);
  const data = await response.json();
  return data;
});

makeRequest('http://example.com/').then(data => {
  console.log(data);
});
```

Conclusion

This chapter covered an extensive set of patterns and examples that can be useful when writing asynchronous code for executing long-running tasks in the background. We saw how callback functions made way for promises, and async/await to execute one or many async tasks.

In the next chapter, we look at another angle of application architecture patterns. We will look at how the patterns for modular development have evolved over time.

Chapter 10. Modular JavaScript Design Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 10th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

In the world of scalable JavaScript, when we say an application is *modular*, we often mean it’s composed of a set of highly decoupled, distinct pieces of functionality stored in modules. **Loose coupling** facilitates easier maintainability of apps by removing *dependencies* where possible. When implemented efficiently, it becomes pretty easy to see how changes to one part of a system may affect another.

In the earlier chapters, we covered the importance of modular programming and the modern way of implementing modular design patterns. While **ES2015** introduced native modules to JavaScript, writing modular JavaScript was still possible before 2015.

In this section, we will look at three formats for modular JavaScript using classic JavaScript (ES5) syntax: AMD, CommonJS, and UMD.

A Note on Script Loaders

It isn't easy to discuss AMD and CommonJS modules without talking about **script loaders**. Script loading was a means to a goal. Modular JavaScript could only be implemented using compatible script loaders.

Several great loaders were available for handling module loading in the AMD and CommonJS formats, but I personally preferred **RequireJS** and **curl.js**.

AMD

The overall goal for the Asynchronous Module Definition (AMD) format is to provide a solution for modular JavaScript that developers could use. It was born out of Dojo's real world experience using XHR+eval, and proponents of this format wanted to avoid any future solutions suffering from the weaknesses of those in the past.

The AMD module format is a proposal for defining modules in which both the module and dependencies can be **asynchronously loaded**. It has several distinct advantages, including being both asynchronous and highly flexible by nature, which removes the tight coupling one might commonly find between code and module identity. Many developers enjoyed using AMD, and one could consider it a reliable stepping stone toward **JavaScript Modules**, which were unavailable at the time.

AMD began as a draft specification for a module format on the CommonJS list, but as it couldn't reach full consensus, further development of the format moved to the **amdjs group**.

It has been embraced by projects including Dojo, MooTools, Firebug, and even jQuery . Although the term *CommonJS AMD format* has been seen in the wild occasionally, it's best to refer to it as just AMD or Async Module support, as not all participants on the CommonJS list wished to pursue it.

NOTE

There was a time when the proposal was referred to as Modules Transport/C. However, as the spec wasn't geared toward transporting existing CommonJS modules but rather—for defining modules—it made more sense to opt for the

AMD naming convention.

Getting Started with Modules

The first two concepts worth noting about AMD are the idea of a `define` method for facilitating module definition and a `require` method for handling dependency loading. `define` is used to define named or unnamed modules based using the following signature:

```
define(  
    module_id /*optional*/,  
    [dependencies] /*optional*/,  
    definition function {} /*function for instantiating the  
    module or object*/  
);
```

As we can tell by the inline comments, the `module_id` is an optional argument that is typically only required when non-AMD concatenation tools are being used (there may be some other edge cases where it's useful, too). When this argument is left out, we refer to the module as *anonymous*.

When working with anonymous modules, the idea of a module's identity is DRY, making it trivial to avoid duplication of filenames and code. Because the code is more portable, it can be easily moved to other locations (or around the file system) without needing to alter the code itself or change its module ID. Consider the `module_id` similar to the concept of folder paths.

NOTE

Developers can run this same code on multiple environments using an AMD optimizer that works with a CommonJS environment such as `r.js`.

Back to the `define` signature, the `dependencies` argument represents an array of dependencies required by the module we are defining, and the third

argument (definition function or factory function) is a function that's executed to instantiate our module. A bare bone module could be defined as follows ([Example 10-1](#)):

Example 10-1. Understanding AMD: define()

```
// A module_id (myModule) is used here for demonstration
purposes only
define( "myModule",

    ["foo", "bar"],

    // module definition function
    // dependencies (foo and bar) are mapped to function
    parameters
    function ( foo, bar ) {
        // return a value that defines the module export
        // (i.e the functionality we want to expose for
        consumption)

        // create your module here
        var myModule = {
            doStuff:function () {
                console.log( "Yay! Stuff" );
            }
        };

        return myModule;
    });

// An alternative version could be..
define( "myModule",

    ["math", "graph"],

    function ( math, graph ) {

        // Note that this is a slightly different pattern
        // With AMD, it's possible to define modules in a few
        // different ways due to it's flexibility with
        // certain aspects of the syntax
        return {
            plot: function( x, y ){
```

```

        return graph.drawPie( math.randomGrid( x, y )
    );
    }
};
});

```

On the other hand, `require` is typically used to load code in a top-level JavaScript file or within a module should we wish to fetch dependencies dynamically. An example of its usage is:

Example 10-2. Understanding AMD: require()

```

// Consider "foo" and "bar" are two external modules
// In this example, the "exports" from the two modules
// loaded are passed as function arguments to the
// callback (foo and bar) so that they can similarly be
// accessed

require(["foo", "bar"], function ( foo, bar ) {
    // rest of your code here
    foo.doSomething();
});

```

The following is an example of a dynamically-loaded dependency (**Example 10-3**):

Example 10-3. Dynamically-loaded dependencies

```

define(function ( require ) {
    var isReady = false, foobar;

    // note the inline require within our module definition
    require(["foo", "bar"], function ( foo, bar ) {
        isReady = true;
        foobar = foo() + bar();
    });

    // we can still return a module
    return {
        isReady: isReady,
        foobar: foobar
    };
});

```

The following is an example of defining an AMD-compatible plug-in (Example 10-4):

Example 10-4. Understanding AMD: plug-ins

```
// With AMD, it's possible to load in assets of almost any  
kind  
// including text-files and HTML. This enables us to have  
template  
// dependencies which can be used to skin components either  
on  
// page-load or dynamically.
```

```
define( [ "../templates",  
"text!../template.md", "css!../template.css" ],  
  
    function( templates, template ){  
        console.log( templates );  
        // do something with our templates here  
    }  
  
));
```

NOTE

Although CSS! is included for loading CSS dependencies in the above example, it's important to remember that this approach has some caveats, such as not being able to establish when the CSS is fully loaded. Depending on how we approach our build process, it may also result in CSS being included as a dependency in the optimized file, so use CSS as a loaded dependency in such cases with caution. If interested in doing the above, we can explore @VIISON's RequireJS CSS plug-in further [here](#).

This example could simply be looked at as `requirejs(["app/myModule"], function(){}),` which indicates the loader's top level globals are being used. This is how to kick off the top-level loading of modules with different AMD loaders. However, with a `define()` function, if it's passed a local `require` all `require([])` examples apply to both types of loader, `curl.js` and `RequireJS` (Examples

Example 10-5, “Loading AMD modules using RequireJS” and Example 10-6, “Loading AMD modules using curl.js”).

Example 10-5. Loading AMD modules using RequireJS

```
require(["app/myModule"],

    function( myModule ){
        // start the main module which in-turn
        // loads other modules
        var module = new myModule();
        module.doStuff();
    });
```

Example 10-6. Loading AMD modules using curl.js

```
curl(["app/myModule.js"],

    function( myModule ){
        // start the main module which in-turn
        // loads other modules
        var module = new myModule();
        module.doStuff();
    });
```

Here is the code for modules with deferred dependencies:

```
<pre xmlns="http://www.w3.org/1999/xhtml"
id="I_programlisting11_id234274"
data-type="programlisting" data-code-language="javascript">
```

```
// This could be compatible with jQuery's Deferred
implementation,
// futures.js (slightly different syntax) or any one of a
number
// of other implementations
```

```
define(["lib/Deferred"], function( Deferred ){
    var defer = new Deferred();

    require(["lib/templates/?index.xhtml", "lib/data/?
stats"],
```

```

        function( template, data ){
            defer.resolve( { template: template, data:data
        } );
        }
    );
    return defer.promise();
});
</pre>

```

AMD Modules with Dojo

Defining AMD-compatible modules using Dojo is pretty straightforward. Define any module dependencies in an array as the first argument and provide a callback (factory) that will execute the module once the dependencies have been loaded. For example:

```

define(["dijit/Tooltip"], function( Tooltip ){

    //Our dijit tooltip is now available for local use
    new Tooltip(...);

});

```

Note the anonymous nature of the module, which can now be both consumed by a Dojo asynchronous loader, RequireJS or the standard `dojo.require()` module loader.

Some interesting gotchas with module referencing are helpful to know here. Although the AMD-advocated way of referencing modules declares them in the dependency list with a set of matching arguments, this isn't supported by the older Dojo 1.6 build system — it only works for AMD-compliant loaders. For example:

```

define(["dojo/cookie", "dijit/Tooltip"], function( cookie,
    Tooltip ){

    var cookieValue = cookie( "cookieName" );
    new Tooltip(...);

```

```
});
```

This has many advantages over nested namespacing , as modules no longer need to reference complete namespaces directly; all we require is the `dojo/cookie` path in dependencies, which once aliased to an argument, can be referenced by that variable. This removes the need to type out `dojo.` in our applications repeatedly.

The final gotcha to be aware of is that if we wish to continue using the older Dojo build system or migrate older modules to this newer AMD-style, the following more verbose version enables easier migration. Notice that `dojo` and `dijit` are referenced as dependencies, too:

```
define(["dojo", "dijit", "dojo/cookie", "dijit/Tooltip"],
function( dojo, dijit){
    var cookieValue = dojo.cookie( "cookieName" );
    new dijit.Tooltip(...);
});
```

AMD Module Design Patterns (Dojo)

As we've seen in previous sections, design patterns can be highly effective in improving how we approach structuring solutions to common development problems. **John Hann** has given some excellent presentations about AMD module design patterns covering the Singleton, Decorator, Mediator, and others. I highly recommend checking out his [slides](#).

A selection of AMD design patterns can be found below (Examples **Example 10-7, "Decorator pattern"** and **Example 10-8, "Adapter pattern"**):

Example 10-7. Decorator pattern

```
// mylib/UpdatableObservable: a Decorator for
dojo/store/Observable
define(["dojo", "dojo/store/Observable"], function ( dojo,
Observable ) {
    return function UpdatableObservable ( store ) {
```

```

        var observable = dojo.isFunction( store.notify ) ?
store :
        new Observable(store);

        observable.updated = function( object ) {
            dojo.when( object, function ( itemOrArray ) {
                dojo.forEach( [].concat(itemOrArray),
this.notify, this );
            });
        };

        return observable;
    });
});

```

```

// Decorator consumer
// a consumer for mylib/UpdatableObservable

define(["mylib/UpdatableObservable"], function (
makeUpdatable ) {
    var observable,
        updatable,
        someItem;

    // make the observable store updatable
    updatable = makeUpdatable( observable ); // `new` is
optional!

    // we can then call .updated() later on if we wish to
pass
    // on data that has changed
    //updatable.updated( updatedItem );
});

```

Example 10-8. Adapter pattern

```

// "mylib/Array" adapts `each` function to mimic jQuery's:
define(["dojo/_base/lang", "dojo/_base/array"], function (
lang, array ) {
    return lang.delegate( array, {
        each: function ( arr, lambda ) {
            array.forEach( arr, function ( item, i ) {

```

```

        lambda.call( item, i, item ); // like
jQuery's each
    });
}
});
});

// Adapter consumer
// "myapp/my-module":
define(["mylib/Array"], function ( array ) {
    array.each( ["uno", "dos", "tres"], function ( i, esp ) {
        // here, `this` == item
    });
});

```

AMD Modules with jQuery

Unlike Dojo, jQuery only comes with one file. However, given the plug-in-based nature of the library, we can demonstrate how straightforward it is to define an AMD module that uses it below.

```

define(["js/jquery.js", "js/jquery.color.js", "js/underscore.
js"],

    function( $, colorPlugin, _ ){
        // Here we've passed in jQuery, the color plugin
        and Underscore
        // None of these will be accessible in the global
        scope, but we
        // can easily reference them below.

        // Pseudo-randomize an array of colors, selecting
        the first
        // item in the shuffled array
        var shuffleColor = _.first( _.shuffle(
"#666", "#333", "#111" ] ) );

        // Animate the background-color of any elements
        with the class
        // "item" on the page using the shuffled color
        $( ".item" ).animate( {"backgroundColor":

```

```

    shuffleColor } );

    // What we return can be used by other modules
    return {};
});

```

However, there is something missing from this example, and it's the registration concept.

Registering jQuery as an Async-compatible module

One of the key features that landed in jQuery 1.7 was support for registering jQuery as an asynchronous module. A number of compatible script loaders (including RequireJS and curl) are capable of loading modules using an asynchronous module format, which means fewer hacks are required to get things working.

If a developer wants to use AMD and does not want her jQuery version leaking into the global space, she should call `noConflict` in their top level module that uses jQuery. In addition, since multiple versions of jQuery can be on a page, there are special considerations that an AMD loader must account for, and so jQuery only registers with AMD loaders that have recognized these concerns, which are indicated by the loader specifying `define.amd.jquery`. RequireJS and curl are two loaders that do so.

The named AMD provides a robust and safe safety blanket for most use cases.

```

// Account for the existence of more than one global
// instances of jQuery in the document, cater for testing
// .noConflict()

var jQuery = this.jQuery || "jQuery",
    $ = this.$ || "$",
    originaljQuery = jQuery,
    original$ = $;

define(["jquery"], function ( $ ) {
    $( ".items" ).css( "background", "green" );

```

```
    return function () {};  
});
```

Why was AMD a better choice for writing modular JavaScript?

We have now reviewed several code samples taking us through what AMD is capable of. It appears to be more than just a typical Module pattern, but why was it a better choice for modular application development?

- Provides a clear proposal for how to approach defining flexible modules.
- Significantly cleaner than the present global namespace and `<script>` tag solutions many of us rely on. There's a clean way to declare standalone modules and dependencies they may have.
- Module definitions are encapsulated, helping us to avoid pollution of the global namespace.
- Arguably works better than some alternative solutions (e.g., CommonJS, which we'll be looking at shortly). It doesn't have issues with cross-domain, local, or debugging and doesn't rely on server-side tools to be used. Most AMD loaders support loading modules in the browser without a build process.
- Provides a "transport" approach for including multiple modules in a single file. Other approaches like CommonJS have yet to agree on a transport format.
- It's possible to lazy load scripts if this is needed.

NOTE

Most of the above points are valid for YUI's module loading strategy.

AMD Conclusions

Having used AMD for several projects, I conclude that it ticks a lot of the checkboxes developers creating serious applications might desire from a better module format. It avoids the need to worry about globals, supports named modules, doesn't require server transformation to function, and is a pleasure to use for dependency management.

It's also an excellent addition for modular development using Backbone.js, ember.js, or other structural frameworks for keeping applications organized.

As AMD was heavily discussed within the Dojo and CommonJS worlds, we know it's had time to mature and evolve. We also know it's been battle-tested in the wild by a number of large companies to build nontrivial applications (IBM, BBC iPlayer), and so, if it didn't work, chances are they would have abandoned it, but didn't.

That said, there are still areas where AMD could have been improved. Developers who used the format for some time may feel the AMD boilerplate/wrapper code was an annoying overhead. While I share this concern, there were tools such as **Volo** that helped work around these issues, and I would argue that on the whole, the pros with using AMD far outweighed the cons.

CommonJS

The CommonJS module proposal specifies a simple API for declaring modules server-side. Unlike AMD, it attempts to cover broader concerns such as io, file-system, promises, and more.

Originally called ServerJS in a project started by Kevin Dangoor back in 2009, the format was later formalized by **CommonJS**, a volunteer working group that aims to design, prototype, and standardize JavaScript APIs. They attempted to ratify standards for both **modules** and **packages**.

Getting Started

From a structural perspective, a CommonJS module is a reusable piece of JavaScript that exports specific objects made available to any dependent code. Unlike AMD, there are typically no function wrappers around such modules (so we won't see `define` here, for example).

CommonJS modules contain two primary parts: a free variable named `exports`, which includes the objects a module wishes to make available to

other modules, and a `require` function that modules can use to import the exports of other modules (Examples [Example 10-9](#), [Example 10-10](#), and [Example 10-11](#)).

Example 10-9. Understanding CommonJS: `require()` and exports

```
CommonJS module

getting started

    require() and exports
    // package/lib is a dependency we require
var lib = require( "package/lib" );

// behaviour for our module
function foo(){
    lib.log( "hello world!" );
}

// export (expose) foo to other modules
exports.foo = foo;
```

Example 10-10. Basic consumption of exports

```
CommonJS module

getting started

    require() and exports
    // package/lib is a dependency we require
var lib = require( "package/lib" );

// behaviour for our module
function foo(){
    lib.log( "hello world!" );
}

// export (expose) foo to other modules
exports.foo = foo;
```

Example 10-11. AMD-equivalent of the first CommonJS example

```
CommonJS module
```

getting started

AMD-equivalent of CommonJS example

AMD module format

AMD-equivalent of CommonJS example

```
define(function(require){
var lib = require( "package/lib" );

// some behaviour for our module
function foo(){
    lib.log( "hello world!" );
}

// export (expose) foo for other modules
return {
    foobar: foo
};
});
```

This can be done as AMD supports a **simplified CommonJS wrapping** feature.

Consuming Multiple Dependencies

app.js:

```
var modA = require( "./foo" );
var modB = require( "./bar" );

exports.app = function(){
    console.log( "Im an application!" );
}

exports.foo = function(){
    return modA.helloWorld();
}
```

bar.js:

```
exports.name = "bar";
```

foo.js:

```
require( "../bar" );  
exports.helloWorld = function(){  
    return "Hello World!!"  
}
```

Is CommonJS Suitable for the Browser?

There are developers that feel CommonJS is better suited to server-side development, which is one reason there was a disagreement over which format should and will be used as the de facto standard before ES2015. Some arguments against CommonJS were that many CommonJS APIs address server-oriented features that one would be unable to implement at a browser level in JavaScript—for example, *io*, *system* and *js* could be considered unimplementable by the nature of their functionality.

That said, it's useful to know how to structure CommonJS modules regardless so that we can better appreciate how they fit in when defining modules that may be used everywhere. Modules with applications on both the client and server include validation, conversion, and templating engines. Some developers approached choosing which format to use by opting for CommonJS when a module can be used in a server-side environment and using AMD if this is not the case.

This makes sense, as AMD modules can use plugins and define more granular things like constructors and functions. CommonJS modules can only define objects which can be tedious to work with if we're trying to obtain constructors from them.

Although it's beyond the scope of this section, you may have noticed that there were different types of `require` methods mentioned when discussing AMD and CommonJS. The concern with a similar naming convention is confusion, and the community is split on the merits of a global `require` function. John Hann's suggestion here is that rather than calling it `require`, which would probably fail to achieve the goal of informing users about the difference between a global and inner `require`, it may make more sense to rename the global loader method something else (e.g., the name of the library). It's for this reason that a loader like `curl.js` uses `curl()` as opposed to `require`.

AMD and CommonJS: Competing, but Equally Valid Standards

Both AMD and CommonJS are valid module formats with different end goals.

AMD adopts a browser-first approach to development, opting for asynchronous behavior and simplified backward compatibility, but it doesn't have any concept of file I/O. It supports objects, functions, constructors, strings, JSON and many other types of modules, running natively in the browser. It's incredibly flexible.

CommonJS, on the other hand, takes a server-first approach, assuming synchronous behavior, no global *baggage*, and attempts to cater to the future (on the server). What I mean by this is that because CommonJS supports unwrapped modules, it can feel a little closer to the ES2015+ specifications, freeing us of the `define()` wrapper that AMD enforces. CommonJS modules, however, only support objects as modules.

UMD: AMD and CommonJS-Compatible Modules for Plug-ins

These solutions could be a little lacking for developers wishing to create modules that can work in browser and server-side environments. To help alleviate this, James Burke, I, and several other developers created Universal Module Definition (UMD; <https://github.com/umdjs/umd>).

UMD is an experimental module format that allows the definition of modules that work in both client and server environments with all or most of the popular script-loading techniques available at the time of writing. Although the idea of (yet) another module format may be daunting, we will cover UMD briefly for thoroughness.

We began defining UMD by looking at the simplified CommonJS wrapper supported in the AMD specification. Developers wishing to write modules as if they were CommonJS modules could use the following CommonJS-

compatible format:

Basic AMD hybrid format

```
define( function ( require, exports, module ){  
    var shuffler = require( "lib/shuffle" );  
    exports.randomize = function( input ){  
        return shuffler.shuffle( input );  
    }  
});
```

It's essential, however, to note that a module is really only treated as a CommonJS module if it doesn't contain a dependency array and the definition function contains one parameter at minimum. This also won't work correctly on some devices (e.g., the PS3). For further information about the above wrapper, see <http://requirejs.org/docs/api.xhtml#cjsmodule>.

Taking this further, we wanted to provide several different patterns that worked with AMD and CommonJS and solved typical compatibility problems developers wishing to develop such modules had with other environments.

One such variation we can see below allows us to use CommonJS, AMD, or browser globals to create a module.

Using CommonJS, AMD, or browser globals to create a module

Define a module `commonJsStrict`, which depends on another module called `b`. The file name implies the module's name, and its best practice for the file name and the exported global to have the same name.

If the module `b` also uses the same boilerplate type in the browser, it will create a global `.b` that is used. If we don't wish to support the browser global patch, we can remove the `root` and pass `this` as the first argument to the top function.

```
(function ( root, factory ) {
```

```

    if ( typeof exports === 'object' ) {
        // CommonJS
        factory( exports, require('b') );
    } else if ( typeof define === 'function' && define.amd
) {
        // AMD. Register as an anonymous module.
        define( ['exports', 'b'], factory);
    } else {
        // Browser globals
        factory( (root.commonJsStrict = {}), root.b );
    }
})(this, function ( exports, b ) {
    //use b in some fashion.

    // attach properties to the exports object to define
    // the exported module properties.
    exports.action = function () {};
}));

```

The UMD repository contains variations covering modules that work optimally in the browser, those best for providing exports, those optimal for CommonJS runtimes, and even those that work best for defining jQuery plug-ins, which we will look at next.

jQuery plug-ins that function in all environments

UMD provides two patterns for working with jQuery plug-ins: one that defines plug-ins that work well with AMD and browser globals and another that can also work in CommonJS environments. jQuery is not likely to be used in most CommonJS environments, so keep this in mind, unless we're working with an environment that does play well with it.

We will now define a plug-in composed of a core and an extension to that core. The core plug-in is loaded into a `$.core` namespace, which can then be easily extended using plug-in extensions via the namespacing pattern. Plug-ins loaded via script tags automatically populate a `plugin` namespace under `core` (i.e., `$.core.plugin.methodName()`).

The pattern can be nice to work with, because plug-in extensions can access properties and methods defined in the base or, with a bit of tweaking,

override default behavior so that it can be extended to do more. A loader is also not required to make any of this fully functional.

For more details of what is being done, please see the inline comments in the code samples below.

    }
})( "core.plugin" , function () {

    // Define our module here and return the public API.
    // This code could be easily adapted with the core to
    // allow for methods that overwrite and extend core
    functionality
    // in order to expand the highlight method to do more
    if we wish.
    return {
        setGreen: function ( el ) {
            highlight(el, "green");
        },
        setRed: function ( el ) {
            highlight(el, errorColor);
        }
    };
}

```

```
    }  
};  
  
});
```

UMD doesn't aim to replace AMD nor CommonJS but merely offers some supplemental assistance for developers wishing to get their code working in more environments today. For further information or to contribute suggestions toward this experimental format, see <https://github.com/umdjs/umd>.

Conclusion

This section reviewed several options for writing modular JavaScript using different module formats before ES2015+.

These formats had several advantages over using the module pattern alone, including avoiding the need to manage global variables, better support for static and dynamic dependency management, improved compatibility with script loaders, better compatibility for modules on the server, and more.

To conclude our discussion of classic design and architecture patterns, I want to touch on one area where we can apply patterns to structure and organize our JavaScript code in the next chapter on Namespacing patterns.

Chapter 11. Namespacing Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 11th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

In this chapter, we will explore patterns for namespacing in JavaScript. Namespaces can be considered a logical grouping of code units under a unique identifier. You can reference the identifier in many namespaces, and each identifier can contain a hierarchy of nested (or sub) namespaces.

In application development, we employ namespaces for many important reasons. JavaScript namespaces help us avoid *collisions* with other objects or variables in the global namespace. They’re also handy for helping organize blocks of functionality in a code base so that it can be more easily referenced and used.

Namespacing any serious script or application is critical, as it’s crucial to safeguard our code from breaking in the event of another script on the page using the *same* variable or method names we are. With the number of *third-party* tags regularly injected into pages, this can be a common problem we all need to tackle at some point in our careers. As a well-behaved “citizen” of the global namespace, it’s also imperative that we try our best not to prevent

other developers' scripts from executing due to the same issues.

While JavaScript doesn't have built-in support for namespaces like other languages, it does have objects and closures that you can use to achieve a similar effect.

Namespacing Fundamentals

You can find namespaces in almost any serious JavaScript application. Unless we're working with a simple code snippet, we must do our best to ensure that we're implementing namespacing correctly, as it's not just easy to pick up; it'll also avoid third-party code destroying our own. The patterns we'll be examining in this section are:

1. Single global variables
2. Prefix namespacing
3. Object literal notation
4. Nested namespacing
5. Immediately-invoked Function
6. Expressions
7. Namespace injection

Single Global Variables

One popular pattern for namespacing in JavaScript is opting for a single global variable as our primary object of reference. You can find a skeleton implementation of this where we return an object with functions and properties below:

```
const myApplication = (() => {  
  function mymethod()  
  {
```

```
    // code  
    return;  
  }  
})();
```

Although this works for certain situations, the biggest challenge with the single global variable pattern is ensuring that no one else has used the same global variable name as we have on the page.

Prefix Namespacing

One solution to the above problem, as mentioned by **Peter Michaux**, is to use prefix namespacing. It's a simple concept at heart, but the idea is we select a unique prefix namespace we wish to use (in this example, `myApplication_`) and then define any methods, variables, or other objects after the prefix as follows:

```
const myApplication_propertyA = {};  
const myApplication_propertyB = {};  
function myApplication_myMethod(){ //...  
}
```

This effectively decreases the chances of a particular variable existing in the global scope, but remember that a uniquely named object can have the same effect.

This aside, the biggest issue with the pattern is that it can result in many global objects once our application grows. There is also a heavy reliance on our prefix not being used by any other developers in the global namespace, so be careful if opting to use this.

For more on Peter's views about the single global variable pattern, read his excellent post: <http://michaux.ca/articles/javascript-namespacing>.

Object Literal Notation

Object literal notation, which we also cover in the Module pattern section, can be thought of as an object containing a collection of key-value pairs with a colon separating each pair of keys and values, where keys can also represent new namespaces.

```
const myApplication = {  
  // As we've seen, we can easily define functionality  
  for  
    // this object literal..  
    getInfo() {  
      //...  
    },  
  
    // but we can also populate it to support  
    // further object namespaces containing anything  
    // anything we wish:  
    models : {},  
    views : {  
      pages : {}  
    },  
    collections : {}  
};
```

One can also opt for adding properties directly to the namespace:

```
myApplication.foo = () => "bar"  
  
myApplication.utils = {  
  toString() {  
    //...  
  },  
  export() {  
    //...  
  }  
}
```

Object literals don't pollute the global namespace but assist in organizing code and parameters logically. They are truly beneficial if you wish to create easily readable structures that you can expand to support deep nesting. Unlike

simple global variables, object literals often consider tests for the existence of a variable by the same name, so the chances of a collision occurring are significantly reduced.

The following sample demonstrates several ways to check if an object namespace already exists, defining it if it doesn't.

```
// This doesn't check for existence of "myApplication" in  
// the global namespace. Bad practice as we can easily  
// clobber an existing variable/namespace with the same  
name  
const myApplication = {};  
  
// The following options *do* check for variable/namespace  
existence.  
// If already defined, we use that instance, otherwise we  
assign a new  
// object literal to myApplication.  
//  
// Option 1: var myApplication = myApplication || {};  
// Option 2  if( !MyApplication ){ MyApplication = {} };  
// Option 3: window.myApplication || ( window.myApplication  
= {} );  
// Option 4: var myApplication = $.fn.myApplication =  
function() {};  
// Option 5: var myApplication = myApplication ===  
undefined ? {} : myApplication;
```

You'll often see developers opting for Option 1 or Option 2—they are both straightforward and equivalent in terms of their results.

Option 3 assumes that you're working in the global namespace, but it can also be written as:

```
myApplication || (myApplication = {});
```

This variation assumes that `myApplication` has already been initialized, so it's only handy for a parameter/argument scenario, as in the following example:

```

function foo() {
  myApplication || ( myApplication = {} );
}

// myApplication hasn't been initialized,
// so foo() throws a ReferenceError

foo();

// However accepting myApplication as an
// argument

function foo( myApplication ) {
  myApplication || ( myApplication = {} );
}

foo();

// Even if myApplication === undefined, there is no error
// and myApplication gets set to {} correctly

```

Options 4 can help write jQuery plug-ins where:

```

// If we were to define a new plug-in..
var myPlugin = $.fn.myPlugin = function() { ... };

// Then later rather than having to type:
$.fn.myPlugin.defaults = {};

// We can do:
myPlugin.defaults = {};

```

This results in better compression (minification) and can save on scope lookups.

Option 5 is a little similar to Option 4 but is a long form that evaluates whether `myApplication` is `undefined` inline—such that it's defined as an object if not—and set to a current value for `myApplication` if so.

It is shown just for the sake of being thorough, but in most situations, Options 1–4 will more than suffice for most needs.

There is, of course, a great deal of variance in how and where object literals are used for organizing and structuring code. For smaller applications wishing to expose a nested API for a particular self-enclosed module, you may just find yourself using the Revealing Module pattern, which we covered earlier in the book:

```
const namespace = (() => {  
  // defined within the local scope  
  const privateMethod1 = () => { /* ... */ };  
  
  const privateMethod2 = () => { /* ... */ };  
  privateProperty1 = "foobar";  
  
  return {  
  
    // the object literal returned here can have as  
many    // nested depths as we wish, however as mentioned,  
    // this way of doing things works best for smaller,  
    // limited-scope applications in my personal  
opinion    publicMethod1: privateMethod1,  
  
    // nested namespace with public properties  
    properties:{  
      publicProperty1: privateProperty1  
    },  
  
    // another tested namespace  
    utils:{  
      publicMethod2: privateMethod2  
    }  
    ...  
  }  
})();
```

The benefit of using object literals here is that they offer us a very elegant key/value syntax to work with; one where we're able to easily encapsulate any distinct logic or functionality for our application in a way that clearly separates it from others and provides a solid foundation for extending our

code.

```
const myConfig = {  
  language: "english",  
  
  defaults: {  
    enableGeolocation: true,  
    enableSharing: false,  
    maxPhotos: 20  
  },  
  
  theme: {  
    skin: "a",  
    toolbars: {  
      index: "ui-navigation-toolbar",  
      pages: "ui-custom-toolbar"  
    }  
  }  
};
```

Note that JSON is a subset of object literal notation, and there are only minor syntactical differences between it and the above (e.g., JSON keys must be strings). If, for any reason, one wishes to use JSON for storing configuration data instead (e.g., for simpler storage when sending to the backend), feel free to. For more on the object literal pattern, I recommend reading Rebecca Murphey's excellent [article on the topic](#), as she covers a few areas we didn't touch upon.

Nested Namespacing

An extension of the object literal pattern is nested namespacing. It's another common pattern that offers a lower risk of collision because even if a namespace already exists, it's unlikely the same nested children do.

For example, something like this!

```
YAHOO.util.Dom.getElementsByClassName("test");
```

Older versions of Yahoo!'s YUI library regularly used the nested object namespacing pattern. During my time as an engineer at AOL, we also used this pattern in many of our larger applications. A sample implementation of nested namespacing may look like this:

```
const myApp = myApp || {};  
  
// perform a similar existence check when defining nested  
// children  
myApp.routers = myApp.routers || {};  
myApp.model = myApp.model || {};  
myApp.model.special = myApp.model.special || {};  
  
// nested namespaces can be as complex as required:  
// myApp.utilities.charting.xhtml15.plotGraph(/*..*/);  
// myApp.modules.financePlanner.getSummary();  
//  
myApp.services.social.facebook.realtimeStream.getLatest();
```

NOTE

The above differs from how YUI3 approaches namespacing. YUI3 modules use a sandboxed API host object with far less and far shallower namespacing.

We can also opt to declare new nested namespaces/properties as indexed properties as follows:

```
myApp["routers"] = myApp["routers"] || {};  
myApp["models"] = myApp["models"] || {};  
myApp["controllers"] = myApp["controllers"] || {};
```

Both options are readable and organized and offer a relatively safe way of namespacing our application, similar to what we may be used to in other languages. The only real caveat is that it requires our browser's JavaScript engine first to locate the `myApp` object and then dig down until it gets to the

function we actually wish to use.

This can mean more work to perform lookups; however, developers such as [Juriy Zaytsev](#) have previously tested and found the performance differences between single object namespacing versus the “nested” approach quite negligible.

Immediately Invoked Function Expressions (IIFE)s

Earlier in the book, we briefly covered the concept of an immediately invoked function expression; **IIFE**, which is effectively an unnamed function, immediately invoked after it’s been defined. If it sounds familiar, it’s because you may have previously come across it referred to as a self-executing (or self-invoked) anonymous function. However, I feel Ben Alman’s IIFE naming is more accurate. In JavaScript, because both variables and functions explicitly defined within such a context may only be accessed inside of it, function invocation provides an easy means to achieving privacy.

IIFEs are a popular approach to encapsulating application logic to protect it from the global namespace, but they also have their use in the world of namespacing.

Examples of IIFEs can be found below:

```
// an (anonymous) immediately-invoked function expression  
(() => { /*...*/ })();
```

```
// a named immediately-invoked function expression  
(function foobar () { /*...*/ })();
```

```
// this is technically a self-executing function which is quite different  
function foobar () { foobar(); }
```

while a slightly more expanded version of the first example might look like this:

```
const namespace = namespace || {};
```

```

// here a namespace object is passed as a function
// parameter, where we assign public methods and
// properties to it
(o => {
  o.foo = "foo";
  o.bar = () => "bar";
})(namespace);

console.log( namespace );

```

While readable, this example could be significantly expanded to address common development concerns such as defined levels of privacy (public/private functions and variables) as well as convenient namespace extension. Let's go through some more code:

```

// namespace (our namespace name) and undefined are passed
// here
// to ensure 1. namespace can be modified locally and isn't
// overwritten outside of our function context
// 2. the value of undefined is guaranteed as being truly
// undefined. This is to avoid issues with undefined being
// mutable pre-ES5.

;((namespace, undefined) => {
  // private properties
  const foo = "foo";

  const bar = "bar";

  // public methods and properties
  namespace.foobar = "foobar";
  namespace.sayHello = () => {
    speak( "hello world" );
  };

  // private method
  function speak(msg) {
    console.log( `You said: ${msg}` );
  };

```

```

    // check to evaluate whether "namespace" exists in the
    // global namespace - if not, assign window.namespace
    an
    // object literal
  })(window.namespace = window.namespace || {});

// we can then test our properties and methods as follows

// public

// Outputs: foobar
console.log( namespace.foobar );

// Outputs: hello world
namespace.sayHello();

// assigning new properties
namespace.foobar2 = "foobar";

// Outputs: foobar
console.log( namespace.foobar2 );

```

Extensibility is of course key to any scalable namespacing pattern and IIFEs can be used to achieve this quite easily. In the below example, our “namespace” is once again passed as an argument to our anonymous function and is then extended (or decorated) with additional functionality:

```

// let's extend the namespace with new functionality
((namespace, undefined) => {

  // public method
  namespace.sayGoodbye = () => {
    console.log( namespace.foo );
    console.log( namespace.bar );
    speak( "goodbye" );
  }
})(window.namespace = window.namespace || {});

// Outputs: goodbye
namespace.sayGoodbye();

```

If you want to learn more about this pattern, I recommend reading Ben's [IIFE post](#) for more information.

Namespace Injection

Namespace injection is another variation on the IIFE in which we “inject” the methods and properties for a specific namespace from within a function wrapper using `this` as a namespace proxy. The benefit this pattern offers is the easy application of functional behavior to multiple objects or namespaces and can come in useful when applying a set of base methods to be built on later (e.g., getters and setters).

The disadvantages of this pattern are that there may be easier or more optimal approaches to achieving this goal (e.g., deep object extension or merging), which I cover earlier in the section.

Below we can see an example of this pattern in action, where we use it to populate the behavior for two namespaces: one initially defined (`utils`) and another which we dynamically create as a part of the functionality assignment for `utils` (a new namespace called `tools`).

```
const myApp = myApp || {};  
myApp.utils = {};  
  
(function () {  
  let val = 5;  
  
  this.getValue = () => val;  
  
  this.setValue = newVal => {  
    val = newVal;  
  }  
  
  // also introduce a new sub-namespace  
  this.tools = {};  
  
}).apply( myApp.utils );  
  
// inject new behaviour into the tools namespace
```

```

// which we defined via the utilities module

(function () {
  this.diagnose = () => "diagnosis"
}).apply( myApp.utils.tools );

// note, this same approach to extension could be applied
// to a regular IIFE, by just passing in the context as
// an argument and modifying the context rather than just
// "this"

// Usage:

// Outputs our populated namespace
console.log( myApp );

// Outputs: 5
console.log( myApp.utils.getValue() );

// Sets the value of `val` and returns it
myApp.utils.setValue( 25 );
console.log( myApp.utils.getValue() );

// Testing another level down
console.log( myApp.utils.tools.diagnose() );

```

Angus Croll has also suggested using the call API to provide a natural separation between contexts and arguments **previously**. This pattern can feel a lot more like a module creator, but as modules still offer an encapsulation solution, we'll briefly cover it for the sake of thoroughness:

```

// define a namespace we can use later
const ns = ns || {};

const ns2 = ns2 || {};

// the module/namespace creator
const creator = function( val ){

  var val = val || 0;

```

```

    this.next = () => val++;

    this.reset = () => {
        val = 0;
    }
};

creator.call( ns );

// ns.next, ns.reset now exist
creator.call( ns2 , 5000 );

// ns2 contains the same methods
// but has an overridden value for val
// of 5000

```

As mentioned, this type of pattern helps assign a similar base set of functionality to multiple modules or namespaces. I would, however, only suggest using it where explicitly declaring functionality within an object/closure for direct access doesn't make sense.

Advanced Namespacing Patterns

We'll now explore some advanced patterns and utilities that I have found invaluable when working on more extensive applications, some of which have required a rethink of traditional approaches to application namespacing. I'll note that I am not advocating the following as *the* way to namespace, but rather ways I have found work in practice.

Automating Nested Namespacing

As we've reviewed, nested namespaces can provide an organized hierarchy of structure for a unit of code. An example of such a namespace could be the following: *application.utilities.drawing.canvas.2d*. This can also be expanded using the object literal pattern to be:

```

const application = {

```

```

        utilities:{
            drawing:{
                canvas:{
                    2d:{
                        //...
                    }
                }
            }
        }
    };

```

One of the obvious challenges with this pattern is that each additional layer we wish to create requires yet another object to be defined as a child of some parent in our top-level namespace. This can become particularly laborious when multiple depths are required as our application increases in complexity.

How can this problem be better solved? In *JavaScript Patterns*, **Stoyan Stefanov** presents a clever approach for automatically defining nested namespaces under an existing global variable. He suggests a convenience method that takes a single string argument for a nest, parses this, and automatically populates our base namespace with the objects required.

The method he suggests using is the following, which I've updated to be a generic function for easier reuse with multiple namespaces:

```

// top-level namespace being assigned an object literal
const myApp = myApp || {};

// a convenience function for parsing string namespaces and
// automatically generating nested namespaces
function extend( ns, ns_string ) {
    const parts = ns_string.split(".");
    let parent = ns;
    let pl;

    pl = parts.length;

    for ( let i = 0; i < pl; i++ ) {
        // create a property if it doesn't exist
        if ( typeof parent[parts[i]] === "undefined" ) {

```

```

        parent[parts[i]] = {};
    }

    parent = parent[parts[i]];
}

return parent;
}

// Usage:
// extend myApp with a deeply nested namespace
const mod = extend(myApp, "myApp.modules.module2");

// the correct object with nested depths is output
console.log(mod);

// minor test to check the instance of mod can also
// be used outside of the myApp namespace as a clone
// that includes the extensions

// Outputs: true
console.log(mod == myApp.modules.module2);

// further demonstration of easier nested namespace
// assignment using extend
extend(myApp, "moduleA.moduleB.moduleC.moduleD");
extend(myApp, "longer.version.looks.like.this");
console.log(myApp);

```

Figure 11-1 shows the Chrome Developer Tools output:

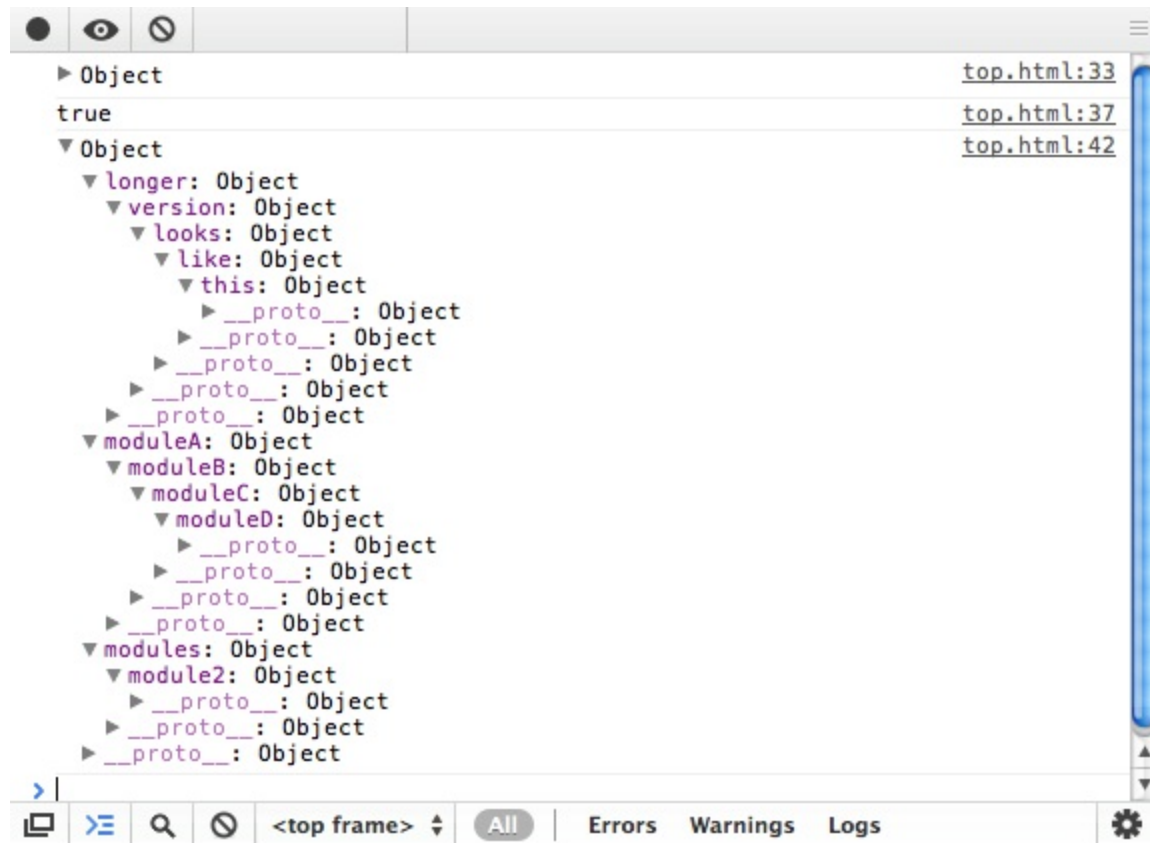

Figure 11-1. Chrome Developer Tools output

Where one would previously have had to explicitly declare the various nests for their namespace as objects, this can now be easily achieved using a single, cleaner line of code.

Dependency Declaration Pattern

We'll now explore a minor augmentation to the Nested Namespacing pattern, which we'll refer to as the Dependency Declaration pattern. We all know that local references to objects can decrease overall lookup times, but let's apply this to namespacing to see how it might look in practice:

```
// common approach to accessing nested namespaces
myApp.utilities.math.fibonacci( 25 );
myApp.utilities.math.sin( 56 );
myApp.utilities.drawing.plot( 98, 50, 60 );

// with local/cached references
```

```
const utils = myApp.utilities;

const maths = utils.math;
const drawing = utils.drawing;

// easier to access the namespace
maths.fibonacci( 25 );
maths.sin( 56 );
drawing.plot( 98, 50, 60 );

// note that the above is particularly performant when
// compared to hundreds or thousands of calls to nested
// namespaces vs. a local reference to the namespace
```

Working with a local variable here is almost always faster than working with a top-level global (e.g., myApp). It's also more convenient and more performant than accessing nested properties/subnamespaces on every subsequent line and can improve readability in more complex applications.

Stoyan recommends declaring localized namespaces required by a function or module at the top of our function scope (using the single-variable pattern) and calls this a Dependency Declaration pattern. One of the benefits this offers is a decrease in locating dependencies and resolving them, should we have an extendable architecture that dynamically loads modules into our namespace when required.

In my opinion, this pattern works best when working at a modular level, localizing a namespace to be used by a group of methods. Localizing namespaces on a per-function level, especially where there is significant overlap between namespace dependencies, is something I recommend avoiding where possible. Instead, define it further up and have them all access the same reference.

Deep Object Extension

An alternative approach to automatic namespacing is deep object extension. Namespaces defined using object literal notation may be easily extended (or merged) with other objects (or namespaces) such that the properties and

functions of both namespaces can be accessible under the same namespace post-merge.

This is something that's been made relatively easy to accomplish with JavaScript frameworks (e.g., see jQuery's `$.extend`); however, if looking to extend objects (namespaces) using vanilla JS, the following routine may be of assistance.

```
// extend.js
// Written by Andrew Dupont, optimized by Addy Osmani

function extend( destination, source ) {
    const toString = Object.prototype.toString;
    const objTest = toString.call({});

    for ( const property in source ) {
        if ( source[property] && objTest ===
toString.call(source[property]) ) {
            destination[property] = destination[property]
|| {};
            extend(destination[property],
source[property]);
        } else {
            destination[property] = source[property];
        }
    }
    return destination;
};

console.group( "objExtend namespacing tests" );

// define a top-level namespace for usage
const myNS = myNS || {};

// 1. extend namespace with a "utils" object
extend(myNS, {
    utils:{
    }
});

console.log( "test 1" , myNS);
```

```

// myNS.utils now exists

// 2. extend with multiple depths
(namespace.hello.world.wave)
extend(myNS, {
    hello:{
        world:{
            wave:{
                test() {
                    //...
                }
            }
        }
    }
});

// test direct assignment works as expected
myNS.hello.test1 = "this is a test";
myNS.hello.world.test2 = "this is another test";
console.log( "test 2", myNS );

// 3. what if myNS already contains the namespace being
added
// (e.g. "library")? we want to ensure no namespaces are
being
// overwritten during extension

myNS.library = {
    foo() {}
};

extend( myNS, {
    library:{
        bar() {
            //...
        }
    }
});

// confirmed that extend is operating safely (as expected)
// myNS now also contains library.foo, library.bar
console.log( "test 3", myNS );

```

```

// 4. what if we wanted easier access to a specific
namespace without having
// to type the whole namespace out each time?

const shorterAccess1 = myNS.hello.world;
shorterAccess1.test3 = "hello again";
console.log( "test 4", myNS);

//success, myApp.hello.world.test3 is now "hello again"

console.groupEnd();

```

NOTE

The above implementation is not cross-browser compatible with all objects and should be considered a proof-of-concept only. One may find the Underscore.js `extend()` method a simpler, more cross-browser-friendly implementation to start with:

<http://documentcloud.github.com/underscore/docs/underscore.xhtml#section-67>. Alternatively, a version of the jQuery `$.extend()` method extracted from the core can be found here: <https://github.com/addyosmani/jquery.parts>.

For developers who are going to use jQuery in their applications, one can achieve the same object namespace extensibility with `$.extend` as follows:

```

// top-level namespace
const myApp = myApp || {};

// directly assign a nested namespace
myApp.library = {
  foo() {
    //...
  }
};

// deep extend/merge this namespace with another
// to make things interesting, let's say it's a namespace
// with the same name but with a different function

```

```

// signature: $.extend( deep, target, object1, object2 )
$.extend( true, myApp, {
    library:{
        bar() {
            //...
        }
    }
});

console.log("test", myApp);
// myApp now contains both library.foo() and library.bar()
// methods
// nothing has been overwritten which is what we're hoping
// for.

```

For thoroughness, please check [this](#) for jQuery `$.extend` equivalents to the rest of the namespacing experiments in this section.

Recommendation

Reviewing the namespace patterns we've explored in this section, the option that I would personally use for most larger applications is nested object namespacing with the Object Literal pattern. Where possible, I would implement this using automated nested namespacing. However, this is just a personal preference.

IIFEs and single global variables may work fine for applications in the small to medium range. However, larger codebases requiring both namespaces and deep subnamespaces require a succinct solution that promotes readability and scale. This pattern achieves all of these objectives well.

I recommend trying out some of the suggested advanced utility methods for namespace extension, as they can save time in the long run.

Conclusion

This chapter discussed how namespacing could help bring structure to your JavaScript and JQuery applications and prevent collisions between variables

and function names. Organizing our project files in large JavaScript applications with many code files helps you better manage modules and namespaces and enhances the development experience.

We have now covered different aspects of design and architecture using plain JavaScript. We have mentioned React in passing but haven't discussed any React patterns in detail. In the next chapter, we aim to do just that.

Chapter 12. React.js Design Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 12th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

Over the years, there has been an increased demand for straightforward ways to compose user interfaces using JavaScript. Front-end developers look for out-of-the-box solutions provided by many different libraries and frameworks. React’s popularity in this area has persevered for a long time now since its original release in 2013. This chapter will look at design patterns that are helpful in the React universe.

React, also referred to as React.js, is an open-source JavaScript library designed by Facebook to build user interfaces or UI components. It is, of course, not the only UI library out there. **Preact**, **Vue**, **Angular**, **Svelte**, **Lit**, and many others are also great for composing interfaces from reusable elements. Given React’s popularity, however, we have chosen it for our discussion on design patterns for the current decade.

An Introduction to React

When front-end developers talk about code, it's most often in the context of designing interfaces for the web. And the way we think of interface composition is in elements like buttons, lists, navigation, etc. React provides an optimized and simplified way of expressing interfaces in these elements. It also helps build complex and tricky interfaces by organizing your interface into three key concepts— components, props, and state.

Because React is composition-focused, it can perfectly map to the elements of your design system. So, designing for React rewards you for thinking in a modular way. It allows you to develop individual components before putting together a page or view, so you fully understand each component's scope and purpose — a process referred to as componentization.

Terminology used

We will use the following terms frequently in this chapter. Lets quickly look at what each of them means.

- React / React.js / ReactJS - React library, created by Facebook in 2013
- ReactDOM - The package for DOM and server rendering
- JSX - Syntax extension to JavaScript
- Redux - Centralized state container
- Hooks - A new way to use state and other React features without writing a class
- ReactNative - The library to develop cross-platform native apps with Javascript
- Webpack - JavaScript module bundler, popular in React community.
- CRA (Create React App) - A CLI tool to create a scaffolding React app for bootstrapping a project.

Basic Concepts

Before we discuss, React design patterns, it would be helpful to understand some basic concepts used in React.

JSX

JSX is an extension to JavaScript which embeds template HTML in JS using XML-like syntax. It is meant to be transformed into valid JavaScript, though the semantics of that transformation are implementation-specific. JSX rose to popularity with the React library but has also seen other implementations.

Components

Components are the building blocks of any React app. They are like JavaScript functions that accept arbitrary input (Props) and return React elements describing what should be displayed on the screen. Everything on screen in a React app is part of a component. Essentially, a React app is just components within components within components. So developers don't build pages in React; they build components. Components let you split your UI into independent, reusable pieces. If you're used to designing pages, thinking from a component perspective might seem like a significant change. But if you use a design system or style guide, this might be a smaller paradigm shift than it looks.

Props

Props are a short form for properties, and they refer to the internal data of a component in React. They are written inside component calls and are passed into components. They also use the same syntax as HTML attributes, e.g., `prop = value`. Two things worth remembering about props are; We determine the value of a prop and use it as part of the blueprint before the component is built. Secondly, the value of a prop will never change, i.e., props are read-only once passed into components. You access a prop by referencing it via the `this.props` property that every component can access.

State

State is an object that holds information that may change over the component's lifetime. It is the current snapshot of data stored in a component's Props. The data can change over time, so techniques to manage data changes become necessary to ensure the component looks the way engineers want it to, at just the right time — this is called State management.

Client-side Rendering

In Client-Side Rendering (CSR), the server renders only the barebones HTML container for a page. The logic, data fetching, templating, and routing required to display content on the page are handled by JavaScript code that executes on the client. CSR became popular as a method of building single-page applications (SPA). It helped to blur the difference between websites and installed applications and works best for highly interactive applications. With React by default, most of the application logic is executed on the client. It interacts with the server through API calls to fetch or save data.

Server-side Rendering

Server-side rendering (SSR) is one of the oldest methods of rendering web content. SSR generates the complete HTML for the page content to be rendered in response to a user request. The content may include data from a data store or external API. React can be rendered isomorphically, which means that it can function both on the browser and other platforms like the server. Thus, UI elements may be rendered on the server using React.

Hydration

In a server-rendered application, HTML for the current navigation is generated on the server and sent to the client. Since the server generated the markup, the client can quickly parse this and display it on the screen. The JavaScript required to make the UI interactive is loaded after this. The event handlers that will make UI elements like buttons interactive

only get attached once the JavaScript bundle is loaded and processed. This process is called hydration. React checks the current DOM nodes and hydrates them with the corresponding JavaScript.

React has evolved over the years. Different features introduced to the library gave rise to various ways of solving common problems. Here are some popular design patterns for React that we will look into in detail in the following sections.

- “Higher Order Components”
- “Render Props Pattern”
- “Hooks Pattern”
- “Static Import”
- “Dynamic Import”
- “Code-splitting”
- “PRPL Pattern”
- “Loading Prioritization”

Higher Order Components

We may often want to use the same logic in multiple components within our application. This logic can include applying specific styling to components, requiring authorization, or adding a global state. One way to reuse the same logic in multiple components is using the Higher Order Component pattern. This pattern allows us to reuse component logic throughout our application.

A Higher Order Component (HOC) is a component that receives another component. The HOC can contain a specific feature that can be applied to a component we pass to it as a parameter. The HOC returns the component with the additional feature applied to it.

Say that we always wanted to add particular styling to multiple components

in our application. Instead of creating a style object locally each time, we can create a HOC that adds the style objects to the component it received as a parameter.

```
function withStyles(Component) {  
  return props => {  
    const style = { padding: '0.2rem', margin: '1rem' }  
    return <Component style={style} {...props} />  
  }  
}  
  
const Button = () = <button>Click me!</button>  
const Text = () => <p>Hello World!</p>  
  
const StyledButton = withStyles(Button)  
const StyledText = withStyles(Text)
```

We just created a StyledButton and StyledText component, the modified versions of the Button and Text component. They now both contain the style that got added in the withStyles HOC.

To take it further, let us look at an application that renders a list of dog images fetched from an API. When fetching the data, we want to show the user a “Loading...” screen. Instead of adding it to the DogImages component directly, we can use a Higher Order Component that adds this logic.

Let’s create a HOC called withLoader. A HOC should receive a component, and return that component. In this case, the withLoader HOC should receive the element which should display Loading... until the data is fetched. To make the withLoader HOC very reusable, we won’t hardcode the Dog API URL in that component. Instead, we can pass the URL as an argument to the withLoader HOC, so this loader can be used on any component that needs a loading indicator while fetching data from a different API endpoint.

```
function withLoader(Element, url) {  
  return props => {};
```

```
}
```

A HOC returns an element, a functional component `props ⇒ {}` in this case, to which we want to add the logic that allows us to display a text with `Loading...` as the data is still being fetched. Once the data has been fetched, the component should pass the fetched data as a prop. The complete code for `withLoader` looks like this.

```
import React, { useEffect, useState } from "react";

export default function withLoader(Element, url) {
  return (props) => {
    const [data, setData] = useState(null);

    useEffect(() => {
      async function getData() {
        const res = await fetch(url);
        const data = await res.json();
        setData(data);
      }

      getData();
    }, []);

    if (!data) {
      return <div>Loading...</div>;
    }

    return <Element {...props} data={data} />;
  };
}
```

We just created a HOC that can receive any component and URL.

- In the `useEffect` hook, the `withLoader` HOC fetches the data from the API endpoint that we pass as the value of `url`. While the data is being fetched, we return the element containing the

text.

- Once the data has been fetched, we set data equal to the data that has been fetched. Since data is no longer `null`, we can display the element that we passed to the HOC.

Now to show the

indicator on the `DogImages` list, we will export the “wrapped” `withLoading` HOC around the `DogImages` component. The `withLoader` HOC also expects the url to know which endpoint to fetch the data from. In this case, we want to add the Dog API endpoint. Since the `withLoader` HOC returned the element with an extra data prop, `DogImages` in this case, we can access the data prop in the `DogImages` component.

```
import React from "react";
import withLoader from "../withLoader";

function DogImages(props) {
  return props.data.message.map((dog, index) => (
    <img src={dog} alt="Dog" key={index} />
  ));
}

export default withLoader(
  DogImages,
  "https://dog.ceo/api/breed/labrador/images/random/6"
);
```

The Higher Order Component pattern allows us to provide the same logic to multiple components while keeping all the logic in one place. The `withLoader` HOC doesn't care about the component or URL it receives: as long as it's a valid component and a valid API endpoint, it'll simply pass the data from that API endpoint to the component that we pass.

Composing

We can also compose multiple Higher Order Components. Let's say we also

want to add functionality that shows a Hovering! text box when the user hovers over the DogImages list.

We must create a HOC that provides a hovering prop to the element we pass. Based on that prop, we can conditionally render the text box based on whether the user is hovering over the DogImages list.

We can now wrap the withHover HOC around the withLoader HOC.

```
export default withHover(  
  withLoader(DogImages,  
    "https://dog.ceo/api/breed/labrador/images/random/6")  
);
```

The DogImages element now contains all props we passed from withHover and withLoader.

We can also use the Hooks pattern to achieve similar results in some cases. We will discuss this pattern in detail later in this chapter but for now, let's just say that - Using Hooks can reduce the depth of the component tree while using the HOC pattern, it's easy to end up with a deeply nested component tree. The best use cases for HOC are those where:

- The same uncustomized behavior needs to be used by many components throughout the application.
- The component can work stand-alone without the added custom logic.

Pros

Using the Higher Order Component pattern allows us to keep logic we want to re-use all in one place. This reduces the risk of accidentally spreading bugs throughout the application by duplicating code repeatedly, potentially introducing new bugs. By keeping the logic in one place, we can keep our code DRY and efficiently enforce the separation of concerns.

Cons

The prop's name that a HOC can pass to an element, can cause a naming collision. For example,

```
function withStyles(Component) {  
  return props => {  
    const style = { padding: '0.2rem', margin: '1rem' }  
    return <Component style={style} {...props} />  
  }  
}  
  
const Button = () = <button style={{ color: 'red' }}>Click  
me!</button>  
const StyledButton = withStyles(Button)
```

In this case, the `withStyles` HOC adds a prop called `style` to the element we pass to it. However, the `Button` component already had a prop called `style`, which will be overwritten! Make sure the HOC can handle accidental name collision, by either renaming or merging the props.

```
function withStyles(Component) {  
  return props => {  
    const style = {  
      padding: '0.2rem',  
      margin: '1rem',  
      ...props.style  
    }  
  
    return <Component style={style} {...props} />  
  }  
}  
  
const Button = () = <button style={{ color: 'red' }}>Click  
me!</button>  
const StyledButton = withStyles(Button)
```

When using multiple composed HOCs that all pass props to the element wrapped within them, it can be challenging to figure out which HOC is responsible for which prop. This can hinder debugging and scaling an application easily.

Render Props Pattern

In the section on Higher Order Components, we saw that reusing component logic can be very convenient if multiple components need access to the same data or contain the same logic.

Another way of making components reusable is by using the render prop pattern. A render prop is a prop on a component whose value is a function that returns a JSX element. The component itself does not render anything besides the render prop. It simply calls the render prop instead of implementing its own rendering logic.

Imagine that we have a Title component that should just render the value we pass. We can use a render prop for this! Let's pass the value we want the Title component to render to the render prop.

```
<Title render={() => <h1>I am a render prop!</h1>} />
```

We can render this data within the Title component by returning the invoked render prop.

```
const Title = props => props.render();
```

We have to pass a prop called `render` to the Component element, which is a function that returns a React element.

```
import React from "react";
import { render } from "react-dom";

import "./styles.css";

const Title = (props) => props.render();

render(
  <div className="App">
    <Title
      render={() => (
        <h1>
          <span role="img" aria-label="emoji">
```

```

        </span>
        I am a render prop!{" "}
        <span role="img" aria-label="emoji">

        </span>
      </h1>
    )}
  />
</div>,
document.getElementById("root")
);

```

The cool thing about render props is that the component receiving the prop is reusable. We can use it multiple times, passing different values to the render prop each time.

Although they're called render props, a render prop doesn't have to be called render. Any prop that renders JSX is considered a render prop. Thus we have three render props in the following example.

```

const Title = (props) => (
  <>
    {props.renderFirstComponent()}
    {props.renderSecondComponent()}
    {props.renderThirdComponent()}
  </>
);

render(
  <div className="App">
    <Title
      renderFirstComponent={() => <h1>First render prop!
</h1>}
      renderSecondComponent={() => <h2> Second render prop!
</h2>}
      renderThirdComponent={() => <h3>Third render prop!
</h3>}
    />
    </div>,
  document.getElementById("root")
)

```

```
);
```

We've just seen that we can use render props to make a component reusable, as we can pass different data to the render prop each time.

A component that takes a render prop usually does much more than simply invoking the render prop. Instead, we typically want to pass data from the component that takes the render prop to the element we pass as a render prop.

```
function Component(props) {  
  const data = { ... }  
  
  return props.render(data)  
}
```

The render prop can now receive this value that we passed as its argument.

```
<Component render={data => <ChildComponent data={data} />} />
```

Lifting state

Before we look at another use-case for the Render Props pattern, let's understand the concept of "Lifting state up" in React.

Let's say we have a temperature converter where you can provide the input in Celcius in one stateful input element. The corresponding Fahrenheit and Kelvin value is reflected instantaneously in two other components. For the input element to be able to share its state with other components, we will have to move the state up to the closest common ancestor of the components that need it. This is called "Lifting state up".

```
function Input({ value, handleChange }) {  
  return <input value={value} onChange={e =>  
    handleChange(e.target.value)} />;  
}  
  
function Kelvin({ value = 0 }) {  
  return <div className="temp">{value + 273.15}K</div>;  
}
```

```

function Fahrenheit({ value = 0 }) {
  return <div className="temp">{(value * 9) / 5 +
32}°F</div>;
}

export default function App() {
  const [value, setValue] = useState("");

  return (
    <div className="App">
      <h1>Temperature Converter</h1>
      <Input value={value} handleChange={setValue} />
      <Kelvin value={value} />
      <Fahrenheit value={value} />
    </div>
  );
}

```

Lifting state is a valuable React state management pattern because sometimes we want a component to be able to share its state with sibling components. In the case of small applications with a few components, we can avoid using a state management library like Redux or React Context and use this pattern instead to lift the state up to the closest common ancestor.

Although this is a valid solution, lifting the state in larger applications with components that handle many children can be tricky. Each state change could cause a re-render of all the children, even those that don't handle the data, which could negatively affect your app's performance. We can use the Render Props pattern to work around this problem. We will change the Input component such that it can receive render props.

```

function Input(props) {
  const [value, setValue] = useState("");

  return (
    <>
      <input
        type="text"
        value={value}

```

```

        onChange={e => setValue(e.target.value)}
        placeholder="Temp in °C"
      />
      {props.render(value)}
    </>
  );
}

export default function App() {
  return (
    <div className="App">
      <h1>Temperature Converter</h1>
      <Input
        render={value => (
          <>
            <Kelvin value={value} />
            <Fahrenheit value={value} />
          </>
        )}
      />
    </div>
  );
}

```

Children as a function

Besides regular JSX components, we can pass functions as children to React components. This function is available to us through the children prop, which is technically also a render prop.

Let's change the Input component. Instead of explicitly passing the render prop, we'll pass a function as a child for the Input component.

```

export default function App() {
  return (
    <div className="App">
      <h1>Temperature Converter</h1>
      <Input>
        {value => (
          <>
            <Kelvin value={value} />

```

```

        <Fahrenheit value={value} />
      </>
    )}
  </Input>
</div>
);
}

```

We have access to this function through the `props.children` prop that's available on the `Input` component. Instead of calling `props.render` with the user input value, we'll call `props.children` with the value of the user input.

```

function Input(props) {
  const [value, setValue] = useState("");

  return (
    <>
      <input
        type="text"
        value={value}
        onChange={e => setValue(e.target.value)}
        placeholder="Temp in °C"
      />
      {props.children(value)}
    </>
  );
}

```

This way, the `Kelvin` and `Fahrenheit` components have access to the value without worrying about the name of the renderprop.

Pros

Sharing logic and data among several components is straightforward with the render props pattern. Components can be made very reusable by using a render or children prop. Although the Higher Order Component pattern mainly solves the same issues, namely reusability and sharing data, the render props pattern solves some problems we could encounter using the HOC pattern.

The issue of naming collisions that we can run into by using the HOC pattern no longer applies by using the render props pattern since we don't automatically merge props. We explicitly pass the props down to the child components with the value provided by the parent component.

Since we explicitly pass props, we solve the HOC's implicit props issue. The props that should get passed down to the element are all visible in the render prop's arguments list. This way, we know exactly where specific props come from. We can separate our app's logic from rendering components through render props. The stateful component that receives a render prop can pass the data onto stateless components, which merely render the data.

Cons

React Hooks have mostly resolved the issues we tried to solve with render props. As Hooks changed how we can add reusability and data sharing to components, they can replace the render props pattern in many cases.

Since we can't add lifecycle methods to a render prop, we can only use it on components that don't need to alter the data they receive.

Hooks Pattern

React 16.8 introduced a new feature called **Hooks**. Hooks make it possible to use React state and lifecycle methods without using an ES2015 class component. Although Hooks are not necessarily a design pattern, Hooks play a vital role in your application design. Hooks can replace many traditional design patterns.

Let us see how the class components enabled the addition of state and lifecycle methods.

Class components

Before Hooks were introduced in React, we had to use class components to add state and lifecycle methods to components. A typical class component in

React can look something like this:

```
class MyComponent extends React.Component {  
  /* Adding state and binding custom methods */  
  constructor() {  
    super()  
    this.state = { ... }  
  
    this.customMethodOne = this.customMethodOne.bind(this)  
    this.customMethodTwo = this.customMethodTwo.bind(this)  
  }  
  
  /* Lifecycle Methods */  
  componentDidMount() { ... }  
  componentWillUnmount() { ... }  
  
  /* Custom methods */  
  customMethodOne() { ... }  
  customMethodTwo() { ... }  
  
  render() { return { ... } }  
}
```

A class component can contain the following:

- A state in its constructor
- Lifecycle methods such as `componentDidMount` and `componentWillUnmount` to perform side effects based on a component's lifecycle
- Custom methods to add extra logic to a class.

Although we can still use class components after the introduction of React Hooks, using class components can have some downsides. For example, consider the following example where a simple div functions as a button.

```
function Button() {  
  return <div className="btn">disabled</div>;  
}
```

Instead of always displaying disabled, we want to change it to enabled and add some extra CSS styling to the button when the user clicks on it. To do that, we need to add state to the component to know whether the status is enabled or disabled. This means we'd have to refactor the functional component entirely and make it a class component that keeps track of the button's state.

```
export default class Button extends React.Component {
  constructor() {
    super();
    this.state = { enabled: false };
  }

  render() {
    const { enabled } = this.state;
    const btnText = enabled ? "enabled" : "disabled";

    return (
      <div
        className={`btn enabled-${enabled}`}
        onClick={() => this.setState({ enabled: !enabled
      })}
      >
        {btnText}
      </div>
    );
  }
}
```

In this example, the component is minimal, and refactoring didn't need much effort. However, your real-life components probably consist of many more lines of code, making refactoring the component much more difficult.

Besides ensuring you don't accidentally change any behavior while refactoring the component, you must also understand how ES2015+ classes work. Knowing how to refactor a component properly without accidentally changing the data flow can be challenging.

Restructuring

The standard way to share code among several components is using the Higher Order Component or Render Props pattern. Although both patterns are valid and using them is a good practice, adding those patterns at a later point in time requires you to restructure your application.

Besides restructuring your app, which is trickier the bigger your components are, having many wrapping components to share code among deeper nested components can lead to something that's best referred to as a wrapper hell. It's not uncommon to open your dev tools and see a structure similar to the following:

```
<WrapperOne>
  <WrapperTwo>
    <WrapperThree>
      <WrapperFour>
        <WrapperFive>
          <Component>
            <h1>Finally in the component!</h1>
          </Component>
        </WrapperFive>
      </WrapperFour>
    </WrapperThree>
  </WrapperTwo>
</WrapperOne>
```

The wrapper hell can make it difficult to understand how data flows through your application, making it harder to figure out why unexpected behavior is happening.

Complexity

As we add more logic to class components, the size of the component increases fast. Logic within that component can get tangled and unstructured, making it difficult for developers to understand where certain logic is used in the class component. This can make debugging and optimizing performance more difficult. Lifecycle methods also require quite a lot of duplication in the

code.

Hooks

Class components aren't always a great feature in React. To solve the common issues that React developers can run into when using class components, React introduced, React Hooks. React Hooks are functions you can use to manage a component's state and lifecycle methods. React Hooks make it possible to:

- Add state to a functional component.
- Manage a component's lifecycle without having to use lifecycle methods such as `componentDidMount` and `componentWillUnmount`
- Reuse the same stateful logic among multiple components throughout the app

First, let's look at how we can add state to a functional component using React Hooks.

State Hook

React provides a hook called `useState` that manages state within a functional component.

Let's see how a class component can be restructured into a functional component using the `useState` hook. We have a class component called `Input`, which renders an input field. The value of input in the state updates whenever the user types anything in the input field.

```
class Input extends React.Component {  
  constructor() {  
    super();  
    this.state = { input: "" };  
  }  
}
```

```

    this.handleInput = this.handleInput.bind(this);
  }

  handleInput(e) {
    this.setState({ input: e.target.value });
  }

  render() {
    <input onChange={handleInput} value={this.state.input}
  />;
  }
}

```

To use the `useState` hook, we need to access React's `useState` method. The `useState` method expects an argument: this is the initial value of the state, an empty string in this case.

We can destructure two values from the `useState` method:

- The *current value* of the state.
- The *method with which we can update* the state.

```
const [value, setValue] = React.useState(initialValue);
```

You can compare the first value to a class component's `this.state`. `[value]`. The second value can be compared to a class component's `this.setState` method.

Since we're dealing with the value of an input, let's call the current value of the state `input` and the method to update the state `setInput`. The initial value should be an empty string.

```
const [input, setInput] = React.useState("");
```

We can now refactor the `Input` class component into a stateful functional component.

```
function Input() {
```

```

const [input, setInput] = React.useState("");

return <input onChange={(e) => setInput(e.target.value)}
value={input} />;
}

```

The input field's value is equal to the current value of the input state, just like in the class component example. When the user types in the input field, the value of the input state updates accordingly using the `setInput` method.

```

import React, { useState } from "react";

export default function Input() {
  const [input, setInput] = useState("");

  return (
    <input
      onChange={e => setInput(e.target.value)}
      value={input}
      placeholder="Type something..."
    />
  );
}

```

Effect Hook

We've seen we can use the `useState` component to handle state within a functional component. Still, another benefit of class components was the possibility of adding lifecycle methods to a component.

With the `useEffect` hook, we can “hook into” a component's lifecycle. The `useEffect` hook effectively combines the `componentDidMount`, `componentDidUpdate`, and `componentWillUnmount` lifecycle methods.

```

componentDidMount() { ... }
useEffect(() => { ... }, [])

componentWillUnmount() { ... }
useEffect(() => { return () => { ... } }, [])

```

```
componentDidUpdate() { ... }  
useEffect(() => { ... })
```

Let's use the input example we used in the State Hook section. Whenever the user is typing anything in the input field, the value should also be logged to the console.

We need a `useEffect` hook that “listens” to the input value. We can do so by adding input to the dependency array of the `useEffect` hook. The dependency array is the second argument that the `useEffect` hook receives.

```
import React, { useState, useEffect } from "react";  
  
export default function Input() {  
  const [input, setInput] = useState("");  
  
  useEffect(() => {  
    console.log(`The user typed ${input}`);  
  }, [input]);  
  
  return (  
    <input  
      onChange={e => setInput(e.target.value)}  
      value={input}  
      placeholder="Type something..."  
    />  
  );  
}
```

The value of the input now gets logged to the console whenever the user types a value.

Custom Hooks

Besides the built-in hooks that React provides (`useState`, `useEffect`, `useReducer`, `useRef`, `useContext`, `useMemo`, `useImperativeHandle`, `useLayoutEffect`, `useDebugValue`, `useCallback`), we can easily create our own custom hooks.

You may have noticed that all hooks start with use. It's essential to begin your hooks with "use" for React to check if it violates the rules of Hooks.

Let's say we want to keep track of specific keys the user may press when writing the input. Our custom hook should be able to receive the key we want to target as its argument.

We want to add a keydown and keyup event listener to the key that the user passed as an argument. If the user presses that key, meaning the keydown event gets triggered, the state within the hook should toggle to true. Else, when the user stops pressing that button, the keyup event gets triggered, and the state toggles to false.

```
function useKeyPress(targetKey) {
  const [keyPressed, setKeyPressed] =
    React.useState(false);

  function handleDown({ key }) {
    if (key === targetKey) {
      setKeyPressed(true);
    }
  }

  function handleUp({ key }) {
    if (key === targetKey) {
      setKeyPressed(false);
    }
  }

  React.useEffect(() => {
    window.addEventListener("keydown", handleDown);
    window.addEventListener("keyup", handleUp);

    return () => {
      window.removeEventListener("keydown", handleDown);
      window.removeEventListener("keyup", handleUp);
    };
  }, []);

  return keyPressed;
}
```

```
}
```

We can use this custom hook in our input application. Let's log to the console whenever the user presses the q, l, or w keys.

```
import React from "react";
import useKeyPress from "../useKeyPress";

export default function Input() {
  const [input, setInput] = React.useState("");
  const pressQ = useKeyPress("q");
  const pressW = useKeyPress("w");
  const pressL = useKeyPress("l");

  React.useEffect(() => {
    console.log(`The user pressed Q!`);
  }, [pressQ]);

  React.useEffect(() => {
    console.log(`The user pressed W!`);
  }, [pressW]);

  React.useEffect(() => {
    console.log(`The user pressed L!`);
  }, [pressL]);

  return (
    <input
      onChange={e => setInput(e.target.value)}
      value={input}
      placeholder="Type something..."
    />
  );
}
```

Instead of keeping the key press logic local to the Input component, we can reuse the useKeyPress hook with multiple components without having to rewrite the same code repeatedly.

Another great advantage of Hooks, is that the community can build and share hooks. We wrote the useKeyPress hook ourselves, but that wasn't

necessary. The hook was already built by someone else and ready to use in our application if we had just installed it.

Here are some websites that list all the hooks built by the community and ready to use in your application.

Additional Hooks guidance

Like other components, special functions are used when you want to add Hooks to the code you have written. Here's a brief overview of some common Hook functions:

useState

The `useState` Hook enables developers to update and manipulate state inside function components without needing to convert it to a class component. One advantage of this Hook is that it is simple and does not require as much complexity as other React Hooks.

useEffect

The `useEffect` Hook is used to run code during major lifecycle events in a function component. The main body of a function component does not allow mutations, subscriptions, timers, logging, and other side effects. It could lead to confusing bugs and inconsistencies within the UI if they are allowed. The `useEffect` Hook prevents all of these “side effects” and allows the UI to run smoothly. It combines `componentDidMount`, `componentDidUpdate`, and `componentWillUnmount`, all in one place.

useContext

The `useContext` Hook accepts a context object, the value returned

from `React.createContext`, and returns the current context value for that context. The `useContext` Hook also works with the React Context API to share data throughout the app without passing your app props down through various levels. Note that the argument passed to the `useContext` Hook must be the context object itself and any component calling the `useContext` always re-renders whenever the context value changes.

useReducer

The `useReducer` Hook gives an alternative to `setState`. It is especially preferable when you have complex state logic that involves multiple sub-values or when the next state depends on the previous one. It takes on a reducer function and an initial state input and returns the current state and a dispatch function as output using array destructuring. `useReducer` also optimizes the performance of components that trigger deep updates.

Pros and Cons of using Hooks

Here are some benefits of making use of Hooks:

- Fewer lines of code Hooks allow you to group code by concern and functionality, not by lifecycle. This makes the code not only cleaner and concise but also shorter. Below is a comparison of a simple stateful component of a searchable product data table using React and how it looks in Hooks after using the `useState` keyword.

Stateful Component

```
class TweetSearchResults extends React.Component {
  constructor(props) {
    super(props);
    this.state = {
      filterText: '',
      inThisLocation: false
    };
  }
}
```

```

        this.handleFilterTextChange =
this.handleFilterTextChange.bind(this);
        this.handleInThisLocationChange =
            this.handleInThisLocationChange.bind(this);
    }

    handleFilterTextChange(filterText) {
        this.setState({
            filterText: filterText
        });
    }

    handleInThisLocationChange(inThisLocation) {
        this.setState({
            inThisLocation: inThisLocation
        })
    }

    render() {
        return (
            <div>
                <SearchBar
                    filterText={this.state.filterText}
                    inThisLocation={this.state.inThisLocation}
                    onFilterTextChange=
{this.handleFilterTextChange}
                    onInThisLocationChange=
{this.handleInThisLocationChange}
                />
                <TweetList
                    tweets={this.props.tweets}
                    filterText={this.state.filterText}
                    inThisLocation={this.state.inThisLocation}
                />
            </div>
        );
    }
}

```

Same component with Hooks

```

const TweetSearchResults = ({tweets}) => {

```

```

    const [filterText, setFilterText] = useState('');
    const [inThisLocation, setInThisLocation] =
useState(false);
    return (
      <div>
        <SearchBar
          filterText={filterText}
          inThisLocation={inThisLocation}
          setFilterText={setFilterText}
          setInThisLocation={setInThisLocation}
        />
        <TweetList
          tweets={tweets}
          filterText={filterText}
          inThisLocation={inThisLocation}
        />
      </div>
    );
  }
}

```

- Simplifies complex components: JavaScript classes can be challenging to manage, hard to use with hot reloading, and may need to be minified better. React Hooks solves these problems and ensures functional programming is made easy. With the implementation of Hooks, We don't need to have class components.
- Reusing stateful logic Classes in JavaScript encourage multiple levels of inheritance that quickly increase overall complexity and potential for errors. However, Hooks allow you to use state and other React features without writing a class. With React, you can always reuse stateful logic without needing to rewrite the code repeatedly. This reduces the chances of errors and allows for composition with plain functions.
- Sharing non-visual logic: Until the implementation of Hooks, React had no way of extracting and sharing non-visual logic. This eventually led to more complexities, such as the HOC patterns and Render props, to solve a common problem. But, the introduction of Hooks has solved this problem because it allows for extracting stateful logic to a simple JavaScript function.

There are of course, some potential downsides to Hooks worth keeping in mind

- Have to respect its rules. With a linter plugin, knowing which rule has been broken is easier.
- Need considerable time practicing to use correctly (e.g., `useEffect`).
- Be aware of the wrong use (e.g., `useCallback`, `useMemo`).

React Hooks vs. Classes

When Hooks were introduced to React, it created a new problem: how do we know when to use function components with Hooks and class components? With the help of Hooks, it is possible to get state and partial lifecycle Hooks even in function components. Hooks allow you to use local state and other React features without writing a class. Here are some differences between Hooks and Classes to help you decide:

- Hooks help avoid multiple hierarchies and make the code clearer. With classes, generally, when you use HOC or `renderProps`, you have to restructure your App with multiple hierarchies when you try to see it in DevTools
- Hooks provide uniformity across React components. Classes confuse humans and machines due to the need to understand binding and the context in which functions are called.

Static Import

The `import` keyword allows us to import code that another module has exported. By default, all modules we're statically importing get added to the initial bundle. A module imported using the default ES2015+ `import` syntax, `import module from [module]`, is statically imported. In this section, we will learn the use of static imports in the React.js context.

Let us look at an example. A simple chat app contains a Chat component, in

which we are statically importing and rendering three components: UserProfile, a ChatList, and a ChatInput to type and send messages. Within the ChatInput module, we're statically importing an EmojiPicker component to show the emoji picker when the user toggles the emoji. We will use **Webpack** to bundle our module dependencies.

```
import React from "react";

// Statically import Chatlist, ChatInput and UserInfo
import UserInfo from "../components/UserInfo";
import ChatList from "../components/ChatList";
import ChatInput from "../components/ChatInput";

import "../styles.css";

console.log("App loading", Date.now());

const App = () => (
  <div className="App">
    <UserInfo />
    <ChatList />
    <ChatInput />
  </div>
);

export default App;
```

The modules get executed as soon as the engine reaches the line on which we import them. When you open the console, you can see the order in which the modules were loaded.

Since the components were statically imported, Webpack bundled the modules into the initial bundle. We can see the bundle that Webpack creates after building the application:

Asset	main.bundle.js
Size	1.5 MiB

Chunks	main [emitted]
Chunk Names	main

Our chat application's source code gets bundled into one bundle: `main.bundle.js`. A large bundle size can significantly affect our application's loading time depending on the user's device and network connection. Before the `App` component can render its contents to the user's screen, it must first load and parse all modules.

Luckily, there are many ways to speed up the loading time! We don't always have to import all modules at once: there may be modules that should only get rendered based on user interaction, like the `EmojiPicker` in this case, or rendered further down the page. Instead of importing all components statically, we can dynamically import the modules after the `App` component has rendered its contents, and the user can interact with our application.

Dynamic Import

The chat application discussed in the previous section on Static Imports had four key components: `UserInfo`, `ChatList`, `ChatInput`, and `EmojiPicker`. However, only three of these components are used instantly on the initial page load: `UserInfo`, `ChatList`, and `ChatInput`. The `EmojiPicker` isn't directly visible and may only be rendered if the user clicks on the `Emoji` to toggle the `EmojiPicker`. This implies that we unnecessarily added the `EmojiPicker` module to our initial bundle, potentially increasing the loading time.

To solve this, we can dynamically import the `EmojiPicker` component. Instead of statically importing it, we'll only import it when we want to show the `EmojiPicker`. An easy way to dynamically import components in React is by using `React Suspense`. The `React.Suspense` component receives the component that should be dynamically loaded, making it possible for the `App` component to render its contents faster by suspending the import of the `EmojiPicker` module. When the user clicks on the `Emoji`, the `EmojiPicker`

component gets rendered for the first time. The EmojiPicker component renders a Suspense component, which receives the lazily imported module: the EmojiPicker in this case. The Suspense component accepts a fallback prop, which receives the component that should get rendered while the suspended component is still loading!

Instead of unnecessarily adding EmojiPicker to the initial bundle, we can split it up into its own bundle and reduce the size of the initial bundle.

A smaller initial bundle size means a faster initial load: the user doesn't have to stare at a blank loading screen for as long. The fallback component lets the user know that our application hasn't frozen: they need to wait a little while for the module to be processed and executed.

Asset	Size	Chunks	Chunk Names
emoji-picker.bundle.js	1.48 KiB	1 [emitted]	emoji-picker
main.bundle.js	1.33 MiB	main [emitted]	main
vendors~emoji-picker.bundle.js	171 KiB	2 [emitted]	vendors~emoji-picker

Whereas previously, the initial bundle was 1.5MiB, we've reduced it to 1.33 MiB by suspending the import of the EmojiPicker. In the console, you can see that the EmojiPicker gets executed once we've toggled the EmojiPicker.

```
import React, { Suspense, lazy } from "react";
// import Send from "../icons/Send";
// import Emoji from "../icons/Emoji";
const Send = lazy(() =>
  import(/*webpackChunkName: "send-icon" */
    "../icons/Send")
);
```

```

const Emoji = lazy(() =>
  import(/*webpackChunkName: "emoji-icon" */
    "./icons/Emoji")
);
// Lazy load EmojiPicker when <EmojiPicker /> renders
const Picker = lazy(() =>
  import(/*webpackChunkName: "emoji-picker" */
    "./EmojiPicker")
);

const ChatInput = () => {
  const [pickerOpen, togglePicker] =
    React.useReducer(state => !state, false);

  return (
    <Suspense fallback={<p id="loading">Loading...</p>}>
      <div className="chat-input-container">
        <input type="text" placeholder="Type a
message..." />
        <Emoji onClick={togglePicker} />
        {pickerOpen && <Picker />}
        <Send />
      </div>
    </Suspense>
  );
};

console.log("ChatInput loaded", Date.now());

export default ChatInput;

```

When building the application, we can see the different bundles that Webpack created. By dynamically importing the `EmojiPicker` component, we reduced the initial bundle size from 1.5MiB to 1.33 MiB! Although the user may still have to wait a while until the `EmojiPicker` has been fully loaded, we have improved the user experience by making sure the application is rendered and interactive while the user waits for the component to load.

Loadable Components

Server-side rendering doesn't support React Suspense (yet). An excellent alternative to React Suspense is the loadable-components library, which you can use in SSR (Server Side Rendered) applications.

```
import React from "react";
import loadable from "@loadable/component";

import Send from "../icons/Send";
import Emoji from "../icons/Emoji";

const EmojiPicker = loadable(() => import("../EmojiPicker"),
{
  fallback: <div id="loading">Loading...</div>
});

const ChatInput = () => {
  const [pickerOpen, togglePicker] = React.useReducer(state
=> !state, false);

  return (
    <div className="chat-input-container">
      <input type="text" placeholder="Type a message..." />
      <Emoji onClick={togglePicker} />
      {pickerOpen && <EmojiPicker />}
      <Send />
    </div>
  );
};

export default ChatInput;
```

Like React Suspense, we can pass the lazily imported module to the loadable, which will only import the module once the EmojiPicker module is requested. While the module is loaded, we can render a fallback component.

Although loadable components are a great alternative to React Suspense for SSR applications, they're also helpful in CSR applications to suspend module imports.

```
import React from "react";
```

```

import Send from "../icons/Send";
import Emoji from "../icons/Emoji";
import loadable from "@loadable/component";

const EmojiPicker = loadable(() =>
import("../components/EmojiPicker"), {
  fallback: <p id="loading">Loading...</p>
});

const ChatInput = () => {
  const [pickerOpen, togglePicker] =
    React.useReducer(state => !state, false);

  return (
    <div className="chat-input-container">
      <input type="text" placeholder="Type a message..."
/>
      <Emoji onClick={togglePicker} />
      {pickerOpen && <EmojiPicker />}
      <Send />
    </div>
  );
};

console.log("ChatInput loaded", Date.now());

export default ChatInput;

```

Import on Interaction

In the chat application example, we dynamically imported the `EmojiPicker` component when the user clicked on the `Emoji`. This type of dynamic import is called **Import on Interaction**. We triggered the component import on interaction by the user.

Import on Visibility

Besides user interaction, we often have components that need not be visible on the initial page load. An excellent example of this is lazy loading images or components that aren't directly visible in the viewport but only get loaded

once the user scrolls down. Triggering a dynamic import when the user scrolls down to a component and it becomes visible is called Import on Visibility.

To know whether components are currently in our viewport, we can use the IntersectionObserver API or libraries such as react-lazyload or react-loadable-visibility to add Import on Visibility to our application quickly. We can now look at the chat application example where the EmojiPicker is imported and loaded when it becomes visible to the user.

```
import React from "react";
import Send from "../icons/Send";
import Emoji from "../icons/Emoji";
import LoadableVisibility from "react-loadable-visibility/react-loadable";

const EmojiPicker = LoadableVisibility({
  loader: () => import("../EmojiPicker"),
  loading: <p id="loading">Loading</p>
});

const ChatInput = () => {
  const [pickerOpen, togglePicker] = React.useReducer(state
=> !state, false);

  return (
    <div className="chat-input-container">
      <input type="text" placeholder="Type a message..." />
      <Emoji onClick={togglePicker} />
      {pickerOpen && <EmojiPicker />}
      <Send />
    </div>
  );
};

console.log("ChatInput loading", Date.now());

export default ChatInput;
```

Code-splitting

In the previous section, we saw how we could dynamically import components when needed. In a complex application with multiple routes and components, we must ensure that our code is bundled and split optimally to allow for a mix of static and dynamic imports at the right time. You can use the Route-based splitting pattern to split your code or rely on modern bundlers such as WebPack or Rollup to split and bundle your application's source code.

Route-based splitting

Specific resources may be only required on certain pages or routes, and we can request resources that are needed only for particular routes by adding route-based splitting. By combining React Suspense or loadable-components with libraries such as react-router, we can dynamically load components based on the current route. For example,

```
import React, { lazy, Suspense } from "react";
import { render } from "react-dom";
import { Switch, Route, BrowserRouter as Router } from
"react-router-dom";

const App = lazy(() => import(/* webpackChunkName: "home"
*/ "./App"));
const Overview = lazy(() =>
  import(/* webpackChunkName: "overview" */ "./Overview")
);
const Settings = lazy(() =>
  import(/* webpackChunkName: "settings" */ "./Settings")
);

render(
  <Router>
    <Suspense fallback={<div>Loading...</div>}>
      <Switch>
        <Route exact path="/">
          <App />
        </Route>
      </Switch>
    </Router>
  , document.getElementById('root'));
```

```

    <Route path="/overview">
      <Overview />
    </Route>
    <Route path="/settings">
      <Settings />
    </Route>
  </Switch>
</Suspense>
</Router>,
document.getElementById("root")
);

module.hot.accept();

```

By lazily loading the components per route, we're only requesting the bundle that contains the code necessary for the current route. Since most people are used to the fact that there may be some loading time during a redirect, it's the perfect place to load components lazily.

Bundle splitting

When building a modern web application, bundlers such as Webpack or Rollup take an application's source code and bundle this together into one or more bundles. When a user visits a website, the bundles required to display the data and features to the user are requested and loaded.

JavaScript engines such as V8 can parse and compile data requested by the user as it's being loaded. Although modern browsers have evolved to parse and compile the code as quickly and efficiently as possible, the developer is still in charge of optimizing the loading and execution time of the requested data. We want to keep the execution time as short as possible to prevent blocking the main thread.

Even though modern browsers can stream the bundle as it arrives, it can still take a significant time before the first pixel is painted on the user's device. The bigger the bundle, the longer it can take before the engine reaches the line on which the first rendering call is made. Until then, the user has to stare at a blank screen, which can be frustrating.

We want to display data to the user as quickly as possible. A larger bundle leads to an increased amount of loading time, processing time, and execution time. It would be great if we could reduce the size of this bundle to speed things up. Instead of requesting one giant bundle that contains unnecessary code, we can split the bundle into multiple smaller bundles. There are some essential metrics that we need to consider when deciding the size of our bundles.

By bundle-splitting the application, we can reduce the time it takes to load, process, and execute a bundle. This, in turn, reduces the time it takes for the first content to be painted on the user's screen, known as the First Contentful Paint. It also reduces the time for the largest component to be rendered to the screen or the Largest Contentful Paint metric.

Although seeing data on our screen is excellent, we want to see more than just the content. To have a fully functioning application, we want users to be able to interact with it as well. The UI only becomes interactive after the bundle has been loaded and executed. The time it takes for all content to be painted on the screen and become interactive is called the Time To Interactive.

A larger bundle doesn't necessarily mean a longer execution time. It could happen that we loaded a ton of code that the user may not even use. Some parts of the bundle will only get executed on a specific user interaction, which the user may or may not do.

The engine still has to load, parse and compile code that's not even used on the initial render before the user can see anything on their screen. Although the parsing and compilation costs can be practically ignored due to the browser's performant way of handling these two steps, fetching a larger bundle than necessary can hurt the performance of your application. Users on low-end devices or slower networks will see a significant increase in loading time before the bundle is fetched.

Instead of initially requesting parts of the code that don't have a high priority in the current navigation, we can separate this code from the code needed to render the initial page.

PRPL Pattern

Making applications accessible to a global user base can be a challenge. The application should be performant on low-end devices and in regions with poor internet connectivity. In order to make sure our application can load as efficiently as possible under challenging conditions, we can use the PRPL pattern.

The PRPL pattern focuses on four primary performance considerations:

- *Pushing* critical resources efficiently minimizes the number of roundtrips to the server and reduces loading time.
- *Rendering* the initial route soon as possible to improve the user experience
- *Pre-caching* assets in the background for frequently visited routes to minimize the number of requests to the server and enable a better offline experience
- *Lazily loading* routes or assets that aren't requested as frequently.

When we visit a website, the browser requests the server for the required resources. The file the entry point points to gets returned from the server, usually our application's initial HTML file. The browser's HTML parser starts to parse this data as soon as it starts receiving it from the server. If the parser discovers that more resources are needed, such as stylesheets or scripts, additional HTTP requests are sent to the server to get those resources.

Requesting resources repeatedly isn't optimal, as we are trying to minimize the number of round trips between the client and the server.

We used HTTP/1.1 for a long time to communicate between the client and the server. Although HTTP/1.1 introduced many improvements compared to HTTP/1.0, such as keeping the TCP connection between the client and the server alive before a new HTTP request gets sent with the keep-alive header, there were still some issues that had to be solved. HTTP/2 introduced

significant changes compared to HTTP/1.1, allowing us to optimize the message exchange between the client and the server.

Whereas HTTP/1.1 used a newline delimited plaintext protocol in the requests and responses, HTTP/2 splits the requests and responses into smaller frames. An HTTP request that contains headers and a body field gets split into at least two frames: a headers frame, and a data frame.

HTTP/1.1 had a maximum amount of 6 TCP connections between the client and the server. Before you can send a new request over the same TCP connection, the previous request must be resolved. If the last request takes a long time to resolve, this request is blocking the other requests from being sent. This common issue is called head-of-line blocking and can increase the loading time of specific resources.

HTTP/2 uses bidirectional streams. A single TCP connection with multiple bidirectional streams can carry multiple request and response frames between the client and the server. Once the server has received all request frames for that specific request, it reassembles them and generates response frames. These response frames are sent back to the client, which reassembles them. Since the stream is bidirectional, we can send both request and response frames over the same stream.

HTTP/2 solves head-of-line blocking by allowing multiple requests to get sent on the same TCP connection before the previous request resolves! HTTP/2 also introduced a more optimized way of fetching data, called server push. Instead of explicitly asking for resources each time by sending an HTTP request, the server can send the additional resources automatically by “pushing” these resources.

After the client has received the additional resources, the resources will get stored in the browser cache. When the resources are discovered while parsing the entry file, the browser can quickly get the resources from the cache instead of making an HTTP request to the server.

Although pushing resources reduces the time to receive additional resources, server push is not HTTP cache-aware. The pushed resources won't be available to us the next time we visit the website, and will have to be

requested again. In order to solve this, the PRPL pattern uses service workers after the initial load to cache those resources to ensure the client isn't making unnecessary requests.

As site authors, we usually know what resources are critical to fetch early on, while browsers do their best to guess this. We can help the browser by adding a preload resource hint to the critical resources.

By telling the browser that you'd like to preload a specific resource, you're telling the browser that you would like to fetch it sooner than the browser would otherwise discover it. Preloading is a great way to optimize the time it takes to load resources critical for the current route.

Although preloading resources is a great way to reduce the number of roundtrips and optimize loading time, pushing too many files can be harmful. The browser's cache is limited, and you may unnecessarily use bandwidth by requesting resources the client didn't need. The PRPL pattern focuses on optimizing the initial load. No other resources get loaded before the initial route is completely rendered.

We can achieve this by code-splitting our application into small, performant bundles. These bundles should allow users to only load the resources they need when they need them while also maximizing cache use.

Caching larger bundles can be an issue. Multiple bundles may share the same resources.

A browser needs help identifying which parts of the bundle are shared between multiple routes and can not cache these resources. Caching resources is vital to reduce the number of roundtrips to the server and to make our application offline-friendly.

When working with the PRPL pattern, we need to ensure that the bundles we're requesting contain the minimal amount of resources we need at that time and are cachable by the browser. In some cases, this could mean that having no bundles at all would be more performant, and we could simply work with unbundled modules.

The benefit of dynamically requesting minimal resources by bundling an

application can easily be mocked by configuring the browser and server to support HTTP/2 push and caching the resources efficiently. For browsers that don't support HTTP/2 server push, we can create an optimized build to minimize the number of roundtrips. The client doesn't have to know whether it's receiving a bundled or unbundled resource: the server delivers the appropriate build for each browser.

The PRPL pattern often uses an app shell as its main entry point, a minimal file containing most of the application's logic and shared between routes. It also includes the application's router, which can dynamically request the necessary resources.

The PRPL pattern ensures that no other resources get requested or rendered before the initial route is visible on the user's device. Once the initial route has been loaded successfully, a service worker can get installed to fetch the resources for the other frequently visited routes in the background!

Since this data is being fetched in the background, the user won't experience any delays. If a user wants to navigate to a frequently visited route cached by the service worker, the service worker can quickly get the required resources from the cache instead of sending a request to the server.

Resources for routes that aren't as frequently visited can be dynamically imported.

Loading Prioritization

The Loading prioritization pattern encourages you to explicitly prioritize the requests for specific resources you know will be required earlier.

Preload (`<link rel="preload">`) is a browser optimization that allows critical resources (that browsers may discover late) to be requested earlier. If you are comfortable thinking about how to order the loading of your key resources manually, it can have a positive impact on loading performance and metrics in the Core Web Vitals. That said, preload is not a panacea and requires an awareness of some trade-offs.

```

<link rel="preload" href="emoji-picker.js" as="script">
...
</head>
<body>
...
<script src="stickers.js" defer></script>
<script src="video-sharing.js" defer></script>
<script src="emoji-picker.js" defer></script>

```

When optimizing for metrics like Time To Interactive or First Input Delay, preload can be helpful to load JavaScript bundles (or chunks) necessary for interactivity. Remember that great care is needed when using preload as you want to avoid improving interactivity at the cost of delaying resources (like hero images or fonts) necessary for First Contentful Paint or Largest Contentful Paint.

If you are trying to optimize the loading of first-party JavaScript, consider using `<script defer>` in the document `<head>` vs. `<body>` to help with the early discovery of these resources.

Preload in single-page apps

While prefetching is a great way to cache resources that may be requested sometime soon, we can preload resources that need to be used instantly. It could be a specific font used on the initial render or certain images the user sees immediately.

Say our `EmojiPicker` component should be visible instantly on the initial render. Although you should not include it in the main bundle, it should get loaded in parallel. Like prefetch, we can add a magic comment to inform Webpack that this module should be preloaded.

```

const EmojiPicker = import(/* webpackPreload: true */
"./EmojiPicker");

```

After building the application, we can see that the `EmojiPicker` will be prefetched. The actual output is visible as a `link` tag with

rel="preload" in the head of our document.

```
<link rel="prefetch" href="emoji-picker.bundle.js"
as="script" />
<link rel="prefetch" href="vendors~emoji-picker.bundle.js"
as="script" />
```

The preloaded `EmojiPicker` could be loaded in parallel with the initial bundle. Unlike prefetch, where the browser still had a say in whether it's got a good enough internet connection and bandwidth to prefetch the resource, a preloaded resource will get preloaded no matter what.

Instead of waiting until the `EmojiPicker` gets loaded after the initial render, the resource will be available to us instantly. As we're loading assets with more thoughtful ordering, the initial loading time may increase significantly depending on your user's device and internet connection. Only preload the resources that must be visible ~1 second after the initial render.

Preload + the async hack

Should you wish for browsers to download a script as high-priority but not block the parser waiting for a script, you can take advantage of the preload + async hack below. The preload, in this case, may delay the download of other resources, but this is a trade-off a developer has to make.

```
<link rel="preload" href="emoji-picker.js" as="script" />
<script src="emoji-picker.js" async></script>
```

Preload in Chrome 95+

The feature is slightly safer thanks to some fixes to preload's queue-jumping behavior in Chrome 95+. Pat Meenan of Chrome's new recommendations for preload suggest:

- Putting it in HTTP headers will jump ahead of everything else.

- Generally, preloads will load in the order the parser gets to them for anything \geq Medium, so be careful putting preloads at the beginning of the HTML.
- Font preloads are probably best towards the end of the head or the beginning of the body
- Import preloads should be done after the script tag that needs the import (so the actual script gets loaded/parsed first)
- Image preloads will have a low priority and should be ordered relative to async scripts and other low/lowest priority tags.

List Virtualization

List Virtualization helps improve the rendering performance of large lists of data. You only render visible rows of content in a dynamic list instead of the entire list. The rows rendered are only a small subset of the full list, with what is visible (the window) moving as the user scrolls. In React, you can achieve this using **react-virtualized**. It's a windowing library by **Brian Vaughn** that renders only the items currently visible in a list (within a scrolling viewport). This means you don't need to pay the cost of thousands of rows of data being rendered at once.

How does Windowing/Virtualization work?

Virtualizing a list of items involves maintaining and moving a window around your list. Windowing in **react-virtualized** works by:

- Having a small container DOM element (e.g., ``) with relative positioning (window)
- Having a big DOM element for scrolling
- Absolutely positioning children inside the container, setting their styles for top, left, width and height.

- Rather than rendering 1000s of elements from a list at once (which can cause slower initial rendering or impact scroll performance), virtualization focuses on rendering just items visible to the user.

This can help keep list rendering fast on mid to low-end devices. You can fetch/display more items as the user scrolls, unloading previous entries and replacing them with new ones.

react-window is a rewrite of react-virtualized by the same author aiming to be smaller, faster, and more tree-shakeable. In a tree-shakeable library, size is a function of which API surfaces you choose to use. I've seen ~20-30KB (gzipped) savings using it in place of react-virtualized. The APIs for both packages are similar; react-window tends to be simpler where they differ.

The following are the main components in the case of **react-window**.

Lists

Lists render a windowed list (row) of elements meaning that only the visible rows are displayed to users. Lists use a Grid (internally) to render rows, relaying props to that inner Grid. The following code snippets show the difference between rendering lists in React Vs. using react-window.

Rendering a list of simple data (`itemsArray`) using React

```
import React from "react";
import ReactDOM from "react-dom";

const itemsArray = [
  { name: "Drake" },
  { name: "Halsey" },
  { name: "Camillo Cabello" },
  { name: "Travis Scott" },
  { name: "Bazzi" },
  { name: "Flume" },
  { name: "Nicki Minaj" },
  { name: "Kodak Black" },
  { name: "Tyga" },
  { name: "Bruno Mars" },
]
```

```

    { name: "Lil Wayne" }, ...
  ]; // our data

const Row = ({ index, style }) => (
  <div className={index % 2 ? "ListItemOdd" :
"ListItemEven"} style={style}>
    {itemsArray[index].name}
  </div>
);

const Example = () => (
  <div
    style=
    class="List"
  >
    {itemsArray.map((item, index) => Row({ index })))}
  </div>
);

ReactDOM.render(<Example />,
document.getElementById("root"));

```

Rendering a list using react-window

```

import React from "react";
import ReactDOM from "react-dom";
import { FixedSizeList as List } from "react-window";

const itemsArray = [...]; // our data

const Row = ({ index, style }) => (
  <div className={index % 2 ? "ListItemOdd" :
"ListItemEven"} style={style}>
    {itemsArray[index].name}
  </div>
);

const Example = () => (
  <List
    className="List"
    height={150}
    itemCount={itemsArray.length}

```

```

        itemSize={35}
        width={300}
      >
        {Row}
      </List>
    );

ReactDOM.render(<Example />,
  document.getElementById("root"));

```

Grid

Grid renders tabular data with virtualization along the vertical and horizontal axes. It only renders the Grid cells needed to fill itself based on current horizontal/vertical scroll positions.

If we wanted to render the same list as earlier with a grid layout, assuming our input is a multi-dimensional array, we could accomplish this using FixedSizeGrid as follows:

```

import React from 'react';
import ReactDOM from 'react-dom';
import { FixedSizeGrid as Grid } from 'react-window';

const itemsArray = [
  [{}, {}, {}, ...],
  [{}, {}, {}, ...],
  [{}, {}, {}, ...],
  [{}, {}, {}, ...],
];

const Cell = ({ columnIndex, rowIndex, style }) => (
  <div
    className={
      columnIndex % 2
        ? rowIndex % 2 === 0
          ? 'GridItemOdd'
          : 'GridItemEven'
        : rowIndex % 2
          ? 'GridItemOdd'
          : 'GridItemEven'
    }
  >

```

```

    }
    style={style}
  >
    {itemsArray[rowIndex][columnIndex].name}
  </div>
);

const Example = () => (
  <Grid
    className="Grid"
    columnCount={5}
    columnWidth={100}
    height={150}
    rowCount={5}
    rowHeight={35}
    width={300}
  >
    {Cell}
  </Grid>
);

ReactDOM.render(<Example />,
document.getElementById('root'));

```

Other Examples

Following are a few other react-window examples

- **Scott Taylor** implemented an open-source **Pitchfork music reviews scraper** using react-window and FixedSizeGrid. Pitchfork scraper uses react-window-infinite-loader, which helps break large data sets down into chunks that can be loaded as they are scrolled into view.
- We found a **The Movie Database (TMDB) demo app** that used react-virtualized and Infinite Loader under the hood. Porting it over to react-window and react-window-infinite-loader took little time, but we did discover a few components still needed to be supported. Regardless, the **final functionality** is close.

Improvements in the web platform

Some modern browsers now support **CSS content-visibility**. `content-visibility:auto` allows you to skip rendering & painting offscreen content until needed. Consider trying the property out if you have a lengthy HTML document with costly rendering.

For rendering lists of dynamic content, I still recommend using a library like react-window. It would be hard to have a `content-visibility:hidden` version of such a library that beats a version aggressively using `display:none` or removing DOM nodes when offscreen like many list virtualization libraries may do today.

Conclusions

Again, use preload sparingly and always measure its impact on production. If the preload for your image is earlier in the document than it is, this can help browsers discover it (and order relative to other resources). When misused, preloading can cause your image to delay First Contentful Paint (e.g., CSS, Fonts)—the opposite of what you want. Also note that for such reprioritization efforts to be effective, it also depends on servers prioritizing requests correctly.

You may also find `<link rel="preload">` helpful for cases where you need to fetch scripts without executing them. A variety of **web.dev** articles touches on how to use Preload to:

- Preload key scripts required for interactivity
- Preload your Largest Contentful Paint image
- Load fonts while preventing layout shifts

Summary

In this chapter, we discussed some essential considerations that drive the

architecture and design of modern web applications. We also saw the different ways in which React.js design patterns address these concerns.

Earlier in this chapter, we introduced the concepts of client-side rendering, server-side rendering, and hydration. JavaScript can have a significant impact on page performance. The choice of rendering techniques can affect how and when the JavaScript is loaded or executed in the page lifecycle. A discussion on Rendering patterns is thus significant when discussing JavaScript patterns and the topic of our next chapter.

Chapter 13. Rendering Patterns

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 13th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

As we moved to more interactive websites, the number of events handled and the amount of content rendered on the client side grew, resulting in single-page applications rendered primarily on the client, as in the case of React.js.

However, webpages can be as static or dynamic as the function they serve. We continue to serve a lot of static content on the web, for example, blog/news pages that you can generate on the server and push as-is to the clients. Static content is stateless, does not fire events, and does not need rehydration after rendering. Conversely, dynamic content (buttons, filters, search bar) has to be rewired to its events after rendering. The DOM has to be regenerated on the client-side (virtual DOM). This regeneration, rehydration, and event handling functions contribute to the JavaScript sent to the client.

A rendering pattern provides the ideal solution for rendering content for a given use case. The following rendering patterns are popular.

Rendering Patterns

<i>Client-Side Rendering (CSR)</i>	HTML is rendered completely on the client
<i>Server-Side Rendering (SSR)</i>	Dynamically rendering HTML content on the server before rehydrating it on the client
<i>Static Rendering</i>	Building a static site to render pages on the the server at build time
<i>Incremental Static Generation</i>	Being able to dynamically augment or modify a static site even after the initial build (Next.js ISR, Gatsby DSG)
<i>Streaming SSR</i>	Breaking down server-rendered content in smaller streamed chunks
<i>Edge Rendering</i>	Altering rendered HTML at the edge before sending it on to the client
<i>Partial Hydration</i>	Only hydrating some of your components on the client (e.g. React Server Components)
<i>Progressive Hydration</i>	Controlling the order of component hydration on the client
<i>Islands Architecture</i>	Isolated islands of dynamic behavior with multiple entry points in an otherwise static site (Astro, Eleventy)
<i>Progressive Enhancement</i>	Making sure an app is functional even without JavaScript

This chapter introduces some of these Rendering patterns and will help you decide which pattern is most suitable for your needs. It will help you make foundational decisions such as:

- How and where do I want to render content?
- Should content be rendered on the web server, build server, on the Edge, or directly on the client?
- Should content be rendered all at once, partially, or progressively?

Importance of Rendering Patterns

Choosing the most suitable rendering pattern for a given use case can make a world of difference to the Developer Experience (DX) you create for the engineering team and the User Experience (UX) you design for your end users. Choosing the correct pattern could lead to faster builds and excellent loading performance at low processing costs. On the other hand, a wrong choice of pattern can kill an app that could have brought to life a great business idea.

To create great UX, we must optimize our apps for user-centric metrics, such as the **Core Web Vitals** (CWV).

Time To First Byte (TTFB)

Time it takes for a client to receive the first byte of page content.

First Contentful Paint (FCP)

Time it takes the browser to render the first piece of content after navigation.

Time To Interactive (TTI)

Time from when the page starts loading to when it responds quickly to

user input.

Largest Contentful Paint (LCP)

Time it takes to load and render the page's main content.

Cumulative Layout Shift (CLS)

Measures visual stability to avoid unexpected layout shift.

First Input Delay (FID)

Time from when the user interacts with the page to the time when the event handlers can run.

The CWV metrics measure parameters most relevant to user experience. Optimizing the CWV can ensure a great user experience and optimal SEO for our apps.

To create a great DX for our product/engineering teams, we have to optimize our development environments by ensuring faster build times, easy rollbacks, scalable infrastructure, and many other features that help developers succeed.

Fast build times

The project should build fast for quick iteration and deployment.

Low server costs

The website should limit and optimize the server execution time to reduce execution costs.

Dynamic content

The page should be able to load dynamic content performantly.

Easy rollbacks

You can quickly revert to a previous build version and deploy it.

Reliable uptime

Users should always be able to visit your website through operational servers.

Scalable infrastructure

Your project may grow or shrink without facing performance issues.

Setting up a development environment based on these principles enables our development teams to build a great product efficiently.

We have now built quite a long list of expectations. But, if you choose the correct rendering pattern, you can get most of these benefits automatically.

Rendering patterns have come a long way, from Server Side Rendering (SSR) and Client Side Rendering (CSR) to highly nuanced patterns discussed and judged today on different forums. While this can get overwhelming, it's important to remember that every pattern was designed to address specific use cases. A pattern characteristic beneficial for one use case can be detrimental in the case of another. It is also quite likely that different types of pages require different rendering patterns on the same website.

The Chrome team has encouraged developers to consider static or server-side rendering over a full rehydration approach. Over time, progressive loading and rendering techniques may help strike a good balance of performance and feature delivery when using a modern framework.

The following sections cover different patterns in detail.

Client Side Rendering

We have already discussed client-side rendering with React in the previous chapter. Here is a brief overview to help us relate it to the other rendering patterns.

With React Client-Side Rendering (CSR), most of the application logic is executed on the client, and it interacts with the server through API calls to fetch or save data. Almost all of the UI is thus generated on the client. The

entire web application is loaded on the first request. As the user navigates by clicking on links, no new request is generated to the server for rendering the pages. The code runs on the client to change the view/data.

CSR allows us to have a Single-Page Application that supports navigation without page refresh and provides a great user experience. As the data processed to change the view is limited, routing between pages is generally faster, making the CSR application seem more responsive.

As the complexity of the page increases to show images, display data from a data store, and include event handling, the complexity, and size of the JavaScript code required to render the page will also increase. CSR resulted in large JavaScript bundles, which increased the FCP and TTI of the page. Large payloads and a waterfall of network requests (e.g., for API responses) may also result in meaningful content not being rendered fast enough for a crawler to index it. This can affect the Search Engine Optimization (SEO) of the website.

Loading and processing excess JavaScript can hurt performance. However, some interactivity and JavaScript are often required, even on primarily static websites. The rendering techniques discussed in the following sections try to find a balance between:

- Interactivity comparable to Client-Side Rendered (CSR) applications
- SEO and performance benefits that are comparable to server-side rendered applications.

Server Side Rendering

With server-side rendering, we generate the HTML for every request. This approach is most suitable for pages containing highly personalized data, for example, data based on the user cookie or generally any data obtained from the user's request. It's also suitable for pages that should be render-blocking, perhaps based on the authentication state.

Server-side rendering (SSR) is one of the oldest methods of rendering web

content. SSR generates the complete HTML for the page content to be rendered in response to a user request. The content may include data from a datastore or external API.

The connect and fetch operations are handled on the server. HTML required to format the content is also generated on the server. Thus, with SSR, we can avoid making additional round trips for data fetching and templating. As such, rendering code is not required on the client and the JavaScript corresponding to this need not be sent to the client.

With SSR, every request is treated independently and processed as a new request by the server. Even if the output of two consecutive requests is not very different, the server will process and generate it from scratch. Since the server is common to multiple users, the processing capability is shared by all active users at a given time.

A personalized dashboard is an excellent example of highly dynamic content on a page. Most of the content is based on the user's identity or authorization level that may be contained in a user cookie. This dashboard only shows when a user is authenticated and possibly shows user-specific sensitive data that should not be visible to others.

The core principle for SSR is that HTML is rendered on the server and shipped with the necessary JavaScript to rehydrate it on the client. Rehydration is regenerating the state of UI components on the client side after the server renders it. Since rehydration comes at a cost, each variation of SSR tries to optimize the rehydration process.

Static Rendering

With static rendering, the HTML for the entire page gets generated at build time and does not change till the next build. The HTML content is static and easily cacheable on a CDN or an Edge network. CDNs can quickly serve the pre-rendered cached HTML to clients when they request a specific page. This considerably cuts down the time it would otherwise take to process the request, render HTML content and respond to a request in a typical server-

side rendering set-up.

The process described above is most suitable for pages that do not change often and display the same data no matter who requests them. Static pages like the ‘About us’, ‘Contact us’, Blog pages for websites, or product pages for e-commerce apps, are ideal candidates for static rendering. Frameworks like Next.js, Gatsby, and VuePress support static generation.

At its core, plain static rendering does not involve any dynamic data. Let us understand it using a Next.js example.

```
// pages/about.js

export default function About() {
  return <div>
    <h1>About Us</h1>
    {/* ... */}
  </div>
}
```

When the site is built (using `next build`), this page will be pre-rendered into an HTML file `about.xhtml` accessible at the route `/about`.

You can have several variations of static rendering as follows:

Static generation of a listing page with dynamic data from a database

The listing page is generated on the server with the data. This is suitable for pages where the listing itself is not very dynamic. In Next.js, you can export the function `getStaticProps()` in the page component for this.

Static generation of detail pages with dynamic routes

Product pages or blog pages usually follow a fixed template with data populated in placeholders. In this case, individual pages can be generated on the server by merging the template with the dynamic data giving us several individual routes for each detailed page. The Next.js **dynamic routes** feature helps to achieve this using the `getStaticPaths()` function.

Static Rendering with Client-Side fetch

This pattern is helpful for a reasonably dynamic listing page that should display fresh listings always. You can still use static rendering for the website to render the UI with a skeleton component where you want to place the dynamic listing data. Then, after the page has loaded, we can fetch the data (using SWR, for example) on the client. A custom API route is used to fetch the data from the CMS and return this data. The pre-generated HTML file is sent to the client when the user requests the page. The user initially sees the skeleton UI without any data. The client fetches the data from the API route, receives the response, and shows the listings.

The key highlights of Static Rendering include the following:

- HTML gets generated at build time
- Easily cacheable by CDN/Vercel Edge Network
- Plain Static Rendering is best for pages that do not require request-based data.
- Static with Client-Side fetch is best for pages that contain data that should refresh on every page load and is contained in stable placeholder components.

Incremental Static Regeneration

ISR is a hybrid of static and server-side rendering because it allows us to pre-render only certain static pages and render the dynamic pages on-demand when the user requests them. This results in shorter build times and allows automatic invalidation of the cache and regeneration of the page after a specific interval.

ISR works on two fronts to incrementally introduce updates to an existing static site after it has been built.

Allows addition of new pages

The lazy loading concept is used to include new pages on the website after the build. This means that the new page is generated immediately on the first request. While the generation takes place, a fallback page or a loading indicator can be shown to the user on the front end.

Update Existing pages

A suitable timeout is defined for every page. This will ensure that the page is revalidated whenever the defined timeout period has elapsed. The timeout could be set to as low as 1 second. The user will continue to see the previous version of the page till the page has finished revalidation. Thus, ISR uses the stale-while-revalidate strategy, where the user receives the cached or stale version while the revalidation takes place. The revalidation occurs entirely in the background and does not need a full rebuild.

On-demand ISR

In this variation of ISR, the regeneration occurs on certain events rather than at fixed intervals. With regular ISR, the updated page is cached only at the edge nodes which have handled user requests for the page. On-demand ISR regenerates and redistributes the page across the edge network so that users worldwide will automatically see the most recent version of the page from the edge cache without seeing stale content. We also avoid unnecessary regenerations and serverless function calls, reducing operational costs compared to regular ISR. Thus On-demand ISR gives us performance benefits and a great DX. On-demand Incremental Static Regeneration is best for pages that should be regenerated based on specific events. It allows us to have fast and dynamic websites that are always online at a reasonable cost.

Summary

Static rendering is an excellent pattern for websites where HTML can be generated at build time. We have now covered different variations of static generation each most suitable for a specific use cases.

Plain Static Rendering

Best for pages that do not contain dynamic data.

Static with Client-Side fetch

Best for pages where data should refresh on every page load and which have stable placeholder components.

Incremental Static Regeneration

Best for pages that should be regenerated on a certain interval or on-demand

On-demand ISR

Best for pages that should be regenerated based on certain events

There are use cases where static isn't the best option. For example, Server-Side rendering is ideal for highly dynamic, personalized pages that are different for every user.

Streaming SSR

With Server-Side Rendering or Static Rendering, you can reduce the amount of JavaScript so that the time taken for the page to become interactive (TTI) is closer to the time for First Contentful Paint (FCP). Streaming the contents can reduce the TTI/FCP further while still server-rendering the application. Instead of generating one large HTML file containing the necessary markup for the current navigation, we can split it into smaller chunks. Node streams allow us to stream data into the response object, which means we can continuously send data down to the client. When the client receives the chunks of data, it can start rendering the contents.

React's built-in `renderToNodeStream` allows us to send our application in smaller chunks. As the client can start painting the UI when it's still receiving data, we can create a very performant first-load experience. Calling

the `hydrate` method on the received DOM nodes will attach the corresponding event handlers, which makes the UI interactive.

Streaming responds well to network backpressure. If the network is clogged and unable to transfer any more bytes, the renderer gets a signal and stops streaming until the network is cleared up. Thus, the server uses less memory and is more responsive to I/O conditions. This enables your Node.js server to render multiple requests simultaneously and prevents heavier requests from blocking lighter requests for a long time. As a result, the site stays responsive even in challenging conditions.

React introduced support for streaming in React 16, released in 2016. It included the following APIs in the `ReactDOMServer` to support streaming.

`ReactDOMServer.renderToNodeStream(element)`

The output HTML from this function is the same as `ReactDOMServer.renderToString(element)` but is in a Node.js readablestream format instead of a string. The function will only work on the server to render HTML as a stream. The client receiving this stream can call `ReactDOM.hydrate()` to hydrate the page and make it interactive.

`ReactDOMServer.renderToStaticNodeStream(element)`

This corresponds to `ReactDOMServer.renderToStaticMarkup(element)`. The HTML output is the same but in a stream format. You can use it to render static, non-interactive pages on the server and then stream them to the client.

The readable stream output by both functions can emit bytes once you start reading from it. You can achieve this by piping the readable stream to a writable stream, such as the response object. The response object progressively sends chunks of data to the client while waiting for new chunks to be rendered.

Edge Server-Side Rendering

Edge Server-Side Rendering enables you to server-render from all regions of a Content Delivery Network (CDN) and experience a near-zero cold boot.

Serverless functions can be used to generate the entire page server-side. The edge runtime also allows HTTP streaming so that you can stream parts of the document as soon as they are ready and hydrate these components granularly. This reduces the time to First Contentful Paint.

A use case for this pattern is building region-specific listing pages for users. The vast majority of the page only contains static data; it's just the listings that require request-based data. Instead of server-rendering the entire page, we can now choose only to render the listing component server-side and the rest edge-side. Whereas we initially had to server-render the whole page to achieve this behavior, we can now get the excellent performance of Static Rendering on the edge with the dynamic benefits of Server-Side Rendering.

Progressive Hydration

Progressive hydration implies you can individually hydrate nodes over time so that you only request the minimum necessary JavaScript at any time. By progressively hydrating the application, we can delay the hydration of less critical parts of the page. This way, we reduce the amount of JavaScript requested to make the page interactive and only hydrate the nodes once the user needs them, for example, when a component is visible in the viewport. Progressive hydration also helps avoid the most common SSR Rehydration pitfalls, where a server-rendered DOM tree is destroyed and immediately rebuilt.

The idea behind progressive hydration is to provide excellent performance by activating your app in chunks. Any progressive hydration solution should also consider how it will impact the overall user experience. You cannot have chunks of the screen popping up one after the other but blocking any activity or user input on the chunks that have already loaded. Thus, the requirements for a holistic progressive hydration implementation are as follows.

- Allows usage of SSR for all components.
- Supports splitting of code into individual components or chunks.
- Supports client side hydration of these chunks in a developer defined sequence.
- Does not block user input on chunks that are already hydrated.
- Allows usage of some loading indicator for chunks with deferred hydration.

React concurrent mode will address all these requirements once it is available. It allows React to work on different tasks simultaneously and switch between them based on the given priority. When switching, a partially rendered tree need not be committed so that the rendering task can continue once React switches back to the same task.

Concurrent mode can be used to implement progressive hydration. In this case, the hydration of each chunk on the page becomes a task for React concurrent mode. If a task of higher priority, like user input, needs to be performed, React will pause the hydration task and switch to accepting the user input. Features like `lazy()` and `Suspense()` allow you to use declarative loading states. These can be used to show the loading indicator while chunks are lazy-loaded. `SuspenseList()` can be used to define the priority for lazy loading components. Dan Abramov has shared a great [demo](#) that shows the concurrent mode in action and implements progressive hydration.

Islands Architecture

Katie Saylor-Miller and Jason Miller popularized the term **Islands architecture** to describe a paradigm that aims to reduce the volume of JavaScript shipped through “islands” of interactivity that can be independently delivered on top of otherwise static HTML. Islands are a component-based architecture that suggests a compartmentalized page view with static and dynamic islands. Most pages are a combination of static and dynamic content. Usually, a page

consists of static content with sprinkles of interactive regions that you can demarcate. The static regions of the page are pure non-interactive HTML and do not need hydration. The dynamic regions are a combination of HTML and scripts capable of rehydrating themselves after rendering.

The Islands architecture facilitates server-side rendering of pages with all of their static content. However, in this case, the rendered HTML will include placeholders for dynamic content. The dynamic content placeholders contain self-contained component widgets. Each widget is similar to an app and combines server-rendered output and JavaScript to hydrate the app on the client.

Islands architecture may be confused with progressive hydration, but there are pretty distinct. In progressive hydration, the hydration architecture of the page is top-down. The page controls the scheduling and hydration of individual components. Each component has its hydration script in the Islands architecture that executes asynchronously, independent of any other script on the page. A performance issue in one component should not affect the other.

Implementing Islands

The Island architecture borrows concepts from different sources and aims to combine them optimally. Template-based static site generators such as **Jekyll** and **Hugo** support rendering static components to pages. Most modern JavaScript frameworks also support **isomorphic rendering**, which allows you to use the same code to render elements on the server and client.

Jason's post suggests using **requestIdleCallback()** to implement a scheduling approach for hydrating components. A framework that supports Islands architecture should:

- Support static rendering of pages on the server with zero JavaScript.
- Support embedding independent dynamic components via placeholders in static content. Each dynamic component contains its scripts and can hydrate itself using **requestIdleCallback()** as soon as the main thread is

free.

- Allow isomorphic rendering of components on the server with hydration on the client to recognize the same component at both ends.

The following frameworks support this to some extent at present.

Marko

Marko is an open-source framework developed and maintained by eBay to improve server rendering performance. It supports Islands architecture by combining streaming rendering with automatic partial hydration. HTML and other static assets are streamed to the client as soon as they are ready. Automatic partial hydration allows interactive components to hydrate themselves. Hydration code is only shipped for interactive components, which can change state on the browser. It is isomorphic, and the Marko compiler generates optimized code depending on where it will run (client or server).

Astro

Astro is a static site builder that can generate lightweight static HTML pages from UI components built in other frameworks such as React, Preact, Svelte, Vue, and others. Components that need client-side JavaScript are loaded individually with their dependencies. Thus it provides built-in partial hydration. Astro can also lazy-load components depending on when they become visible.

Eleventy + Preact

Markus Oberlehner demonstrates the use of Eleventy, a static site generator with isomorphic Preact components that can be partially hydrated. It also supports lazy hydration. The component itself declaratively controls its hydration. Interactive components use a `WithHydration` wrapper so that they are hydrated on the client.

Note that Marko and Eleventy pre-date the definition of Islands provided by Jason but contain some of the features required to support it. *Astro*, however,

was built based on the definition and inherently supports the Islands architecture.

Pros and Cons

Some of the potential benefits of implementing islands are as follows.

Performance

Reduces the amount of JavaScript code shipped to the client. The code sent only consists of the script required for interactive components. This is considerably less than the script needed to recreate the virtual DOM for the entire page and rehydrate all the elements. The smaller size of JavaScript automatically corresponds to faster page loads.

SEO

Since all the static content is rendered on the server, pages are SEO-friendly.

Prioritizes important content

Key content (especially for blogs, news articles, and product pages) is available almost immediately to the user.

Accessibility

Using standard static HTML links to access other pages helps to improve the accessibility of the website.

Component-based

The design offers all advantages of component-based architecture, such as reusability and maintainability.

Despite the advantages, the concept is still in a nascent stage. The only options for developers to implement Islands are to use one of the few available frameworks or develop the architecture yourself. Migrating existing

sites to Astro or Marko would require additional efforts. The architecture is also unsuitable for highly interactive pages like social media apps which would probably require thousands of islands.

React Server Components

The React team is working on zero-bundle-size React Server Components, which aim to enable modern UX with a server-driven mental model. This is quite different from Server-side Rendering (SSR) of components and could result in significantly smaller client-side JavaScript bundles.

With React Server Components, our components can be re-fetched regularly. An application with components that rerender when there is new data can be run on the server, limiting how much code needs to be sent to the client.

[RFC]: Developers constantly have to make choices about using third-party packages. Using a package to render some markdown or format a date is convenient for us as developers, but it increases code size and hurts performance for our users

React's new Server Components compliment Server-side rendering, enabling rendering into an intermediate abstraction format without needing to add to the JavaScript bundle. This allows merging the server-tree with the client-side tree without a loss of state and enables scaling up to more components.

Server Components are not a replacement for SSR. When paired together, they support quickly rendering in an intermediate format, then having Server-side rendering infrastructure rendering this into HTML, enabling early paints to still be fast. We SSR the Client components, which the Server components emit, similar to how SSR is used with other data-fetching mechanisms.

This time, however, the JavaScript bundle will be significantly smaller. Early explorations have shown that bundle size wins could be significant (-18-29%), but the React team will have a clearer idea of wins in the wild once further infrastructure work is complete.

Server Components is still experimental, but the React team is working with

frameworks like Next.js, Hydrogen, and Remix to advance the proposal and get it ready for broad adoption.

Conclusion

This chapter introduced many patterns that attempt to balance the capabilities of CSR and SSR. Depending on the type of the application or the page type, some of the patterns may be more suitable than the others. The following chart compares the highlights of different patterns and provides use cases for each.

Figure 13-1. Rendering patterns

The following table from **Patterns for Building JavaScript Websites in 2022** offers another view pivoted by key application characteristics. It should be helpful for anyone looking for a suitable pattern for common **application holotypes**.

Portfolio	Content	Storefront	Social Network
-----------	---------	------------	----------------

Holotype	Personal Blog	CNN	Amazon	Social Netwo

We have now discussed some interesting React patterns for components, state management, rendering, and others. Libraries like React do not enforce a specific application structure, but there are recommended best practices for organizing your React projects. Let us explore this in the next chapter.

Chapter 14. Application Structure for React.js

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 14th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

When building small hobby projects or trying a new concept or library, developers can start adding files to a folder without a plan or organizing structure. These could include CSS, helper components, images, and pages. A single folder for all resources becomes unmanageable as the project grows. Any respectably sized codebase should be organized into an application folder structure based on logical criteria. The decision on how to structure your files and application components could be a personal/team choice. It would also generally depend on the application domain and technology used.

This chapter mainly focuses folder structures for React.js applications that could help in better management of our projects as they grow.

Introduction

React.js itself does not provide a guideline on structuring projects but does suggest a few commonly used approaches. Let us look at these and

understand their pros and cons before discussing folder structures for projects with added complexities and Next.js applications.

At the high level, you can group files in a React application in **two ways**.

Group By feature

Create folders for every application module, feature, or route

Group By file type

Create folders for different types of files

Let us look at this classification in detail.

Group By module, feature, or route

In this case, the file structure would mirror the business model or the application flow. For example, if you have an e-commerce application, you will have folders for product, productlist, checkout, etc. The CSS, jsx components, tests, sub-components, or helper libraries explicitly required for the product module reside in the product folder.

```
common/  
  Avatar.js  
  Avatar.css  
  ErrorUtils.js  
  ErrorUtils.test.js  
product/  
  index.js  
  product.css  
  price.js  
  product.test.js  
checkout/  
  index.js  
  checkout.css  
  checkout.test.js
```

The advantage of grouping files by feature is that if there is a change to the

module, all the affected files are co-located in the same folder, and the change gets localized to a specific part of the code.

The disadvantage is common components, logic, or styles used across modules should be identified periodically to avoid repetition and promote consistency and reuse.

Group by file type

In this type of grouping, you would create different folders for CSS, components, test files, images, libraries, etc. Thus, logically related files would reside in different folders based on the file type.

```
css/  
  global.css  
  checkout.css  
  product.css  
lib/  
  date.js  
  currency.js  
  gtm.js  
pages/  
  product.js  
  productlist.js  
  checkout.js
```

The advantages of this approach are

- You have a standard structure that you can reuse across projects.
- Newer team members with little knowledge of the application-specific logic can still find files for something like styles or tests.
- Common components (such as date-pickers) and styles imported in different routes or modules can be changed once to ensure that the effect is seen across the application.

The disadvantages are

- A change in logic for a specific module would likely require changes in files across different folders.
- As the number of features in the application grows, the number of files in different folders would increase, making it difficult to find a specific file.

Either of these approaches could be easy to set up for small to mid-sized applications with a small number of files (50 to 100) per folder. For larger projects, however, you may want to go for a hybrid approach based on the logical structure of your application. Let us look at some of the possibilities.

Hybrid grouping based on domain and common components

Here you would group all common components required across the application in a Components folder and all application flow-specific routes or features in a **domain folder** (the name could be domain, pages, or routes). Every folder can have subfolders for specific components and related files.

```
css/  
  global.css  
components/  
  User/  
    profile.js  
    profile.test.js  
    avatar.js  
  date.js  
  currency.js  
  gtm.js  
  errorUtils.js  
domain/  
  product/  
    product.js  
    product.css  
    product.test.js  
  checkout/  
    checkout.js  
    checkout.css
```

```
checkout.test.js
```

Thus, you can combine the advantages of both Group by file type and Group by feature by co-locating related files, which change together frequently and common reusable components and styles used across the application.

Depending on the complexity of the application, you can modify this to a flatter structure without subfolders or a more nested structure.

Flatter structure

The following example illustrates a flatter structure.

```
[source, ]
----
domain/
    product.js
    product.css
    product.test.js
    checkout.js
    checkout.css
    checkout.test.js
----
```

Nested structure

The following example shows a more nested structure.

```
[source, ]
----
domain/
    product/
```

```
productType/  
  features.js  
  features.css  
  size.js  
price/  
  listprice.js  
  discount.js
```

NOTE

It's best to avoid deep nesting with more than three to four levels as it becomes harder to write relative imports between folders or update those imports when the files are moved.

A variation to this approach is to create folders based on views or routes, in addition to those based on domain, as discussed [here](#). A routing component can then coordinate the view to be displayed based on the current route.

[Next.js](#) uses a similar structure.

Application Structure for modern React features

Modern React apps use different features such as Redux, stateful containers, hooks, and Styled Components. Let us see where the code related to these would fit in the application structure proposed in the previous section.

Redux

Redux documentation [strongly recommends](#) co-locating logic for a given feature in one place. Within a given feature folder, the Redux logic for that feature should be written as a single “slice” file, preferably using the Redux

Toolkit createSlice API. The file bundles {actionTypes, actions, reducer} to a self-contained, isolated module. This is also known as the “ducks” pattern (from Redux). For example, as given [here](#).

```
/src
  index.tsx: Entry point file that renders the React
  component tree
  /app
    store.ts: store setup
    rootReducer.ts: root reducer (optional)
    App.tsx: root React component
  /common: hooks, generic components, utils, etc
  /features: contains all "feature folders"
  /todos: a single feature folder
    todosSlice.ts: Redux reducer logic and associated
  actions
    Todos.tsx: a React component
```

Another comprehensive example that uses Redux without creating containers or hooks is available [here](#).

Containers

If you have structured your code to categorize components into **presentational components and stateful container components**, you can create a separate folder for the container components. Containers let you separate complex stateful logic from other aspects of the component.

```
/src
  /components
    /component1
      index.js
      styled.js

  /containers
    /container1
```

You can find a complete structure for an app with containers [here](#).

Hooks

Hooks can fit into the hybrid structure just like any other type of code. You can have a folder at the app level for common hooks that can be consumed by all React components. React Hooks only used by one component should remain in the component's file or a separate `hooks.js` file in the component's folder. You can find a sample structure [here](#).

```
/components
  /productList
    index.js
    test.js
    style.css
    hooks.js

/hooks
  /useClickOutside

Styled components

If you are using Styled Components instead of CSS, you can have `style.js` files instead of the component-level CSS files mentioned earlier. For example, if you have a `[.keep-together]# titlebar#` component, the structure would be something like this.

```
/src/components/button/
  index.js
  style.js
```

An application-level `theme.js` file would contain the values for colors to be used for background and text. A `globals` component could include definitions for common style elements that other components can use.

Other best practices

In addition to folder structure, some other best practices that you can consider when structuring your React applications are as follows.

- Use **import aliasing** to help with long relative paths for common imports. This can be done using both Babel and **Webpack** configuration.
- **Wrap** third-party libraries with your API so that they can be swapped if required
- Use **PropTypes** with components to ensure type checking for property values.

Build performance depends on the number of files and dependencies. If you are using a bundler such as Webpack, a few suggestions for improving build times may be helpful.

When using a **loader**, apply it to only those modules that need to be transformed by it. For example,

```
const path = require('path');

module.exports = {
  //...
  module: {
    rules: [
      {
        test: /\.js$/,
        include: path.resolve(__dirname, 'src'),
        loader: 'babel-loader',
      },
    ],
  },
};
```

If you are using hybrid/nested folder structures, the following **example** from WebPack shows how to include and load files from different paths in the structure.

```
const path = require('path');
```

```

module.exports = {
  //...
  module: {
    rules: [
      {
        test: /\.css$/,
        include: [
          // Include paths relative to the current
          // directory starting with `app/styles` e.g. `app/styles.css`,
          // `app/styles/styles.css`, `app/stylesheet.css`
          path.resolve(__dirname, 'app/styles'),

          // add an extra slash to only include the content
          // of the directory `vendor/styles/`
          path.join(__dirname, 'vendor/styles/'),
        ],
      },
    ],
  },
};

```

Files which do not have an `import`, `require`, `define` etc to reference other modules, need not be parsed for dependencies. You can avoid parsing them using the `noparse` option.

Application Structure for Next.js apps

Next.js is a production-ready framework for scalable React apps. While you can use the hybrid structures, all the routes in the app must be grouped under the `pages` folder. (URL of the page = the root URL + relative path in the `pages` folder).

Extending the structures discussed previously, you can have folders for common components, styles, hooks, utility functions. Code related on account of the domain can be structured into functional components that different routes can use. Finally, you will have the `pages` folder for all routes. Here's an example for this based on [this guide](#).

```

--- public/

```

```
Favicon.ico
images/
--- common/
    components/
        datePicker/
            index.js
            style.js
    hooks/
    utils/
    styles/
--- modules/
    auth/
        auth.js
        auth.test.js
    product/
        product.js
        product.test.js
--- pages/
    _app.js
    _document.js
    index.js
        /products
        [id].js
```

Next.js also provides **examples** for many different types of apps. You can bootstrap these using Create-Next-app to create the template folder structure provided by Next.js. For example, to create the template for a basic **blog** app use.

```
yarn create next-app --example blog my-blog
```

Summary

This chapter discussed multiple different options for structuring React projects. Depending on the size, type, and components used in the project, you can choose the one most relevant to yours. Sticking to a defined pattern for structuring a project would help you explain it to other team members and prevent projects from getting disorganized and unnecessarily complicated.

The next chapter is the concluding chapter of this book and provides additional links that might be helpful when learning about JavaScript design patterns.

Chapter 15. Conclusions

A NOTE FOR EARLY RELEASE READERS

With Early Release ebooks, you get books in their earliest form—the author’s raw and unedited content as they write—so you can take advantage of these technologies long before the official release of these titles.

This will be the 15th chapter of the final book.

If you have comments about how we might improve the content and/or examples in this book, or if you notice missing material within this chapter, please reach out to the editor at mcronin@oreilly.com.

That’s it for this introductory adventure into the world of design patterns in JavaScript and React. I hope you’ve found it beneficial.

Design patterns make it easy for us to build on the shoulders of developers who have defined solutions to challenging problems and architectures over a several decades. The contents of this book should hopefully provide sufficient information to get you started using the patterns we covered in your scripts, plug-ins, and web applications.

We need to be aware of these patterns, but it’s also essential to know how and when to use them. Study the pros and cons of each pattern before employing them. Take the time to experiment with patterns to fully appreciate what they offer and make usage judgements based on a pattern’s actual value to your application.

If I’ve encouraged your interest in this area further and you would like to learn more about design patterns, there are many excellent titles available for generic software development and, of course, JavaScript.

I am happy to recommend the following:

- **Patterns Of Enterprise Application Architecture** by Martin Fowler
- **JavaScript Patterns** by Stoyan Stefanov

Thanks for reading *Learning JavaScript Design Patterns*. For more educational material on learning JavaScript, please read more from me on my blog at <http://addyosmani.com> or on Twitter [@addyosmani](https://twitter.com/addyosmani).

Until next time, the very best of luck with your adventures in JavaScript!
